The aPTT is the most common test used for monitoring UFH therapy, although the evidence for adjusting the UFH dose to maintain a therapeutic aPTT range is based on a post hoc analysis of a prospective descriptive study. Most patients evaluated (n = 162) were receiving heparin therapy for venous thromboembolism (VTE). Heparin was titrated to an aPTT between 1.5 and 2.5 times control values, and the analysis showed that an aPTT greater than 1.5 times control was associated with reduced recurrent VTE. Therefore, this goal aPTT range became widely accepted in clinical practice. Unfortunately, this therapeutic range has not been confirmed by a randomized clinical trial, and it does not account for significant variability in the aPTT test observed both within and between institutions. Because of this, the goal therapeutic aPTT range varies, depending on the aPTT reagent, the instrument, and the reagent’s responsiveness to each lot of UFH. Therefore, the traditional reported therapeutic range of 60–80 seconds (e.g., about 1.5–2.5 times control) cannot accurately be used within hospital settings without evaluation of a specific aPTT reagent’s sensitivity to heparin. The therapeutic range is calculated using a regression analysis evaluating values obtained from samples containing known levels of heparin and samples from patients on UFH therapy by aPTT versus the anti-factor Xa (anti-Xa) activity (e.g., heparin levels). In the original study described previously, the investigators established that an aPTT ratio of 1.5–2.5 corresponded to a heparin level of 0.2–0.4 international units/mL by protamine titration and a heparin level of 0.3–0.7 international units/mL measured by anti-Xa assay. Therefore, most institutions set their aPTT goal range for VTE at 0.3–0.7 international units/mL of anti-Xa activity (Figure 25.4). The goal therapeutic aPTT range for other UFH
indications is less clear, which commonly results in a variety of goal ranges depending on the type of critically ill patient and the therapeutic end points. The sensitivity of a reagent will determine the aPTT response, with more sensitive reagents resulting in steeper regression slopes and higher aPTT goal ranges. It is important for institutions to use plasma samples from patients on heparin treatment rather than simply using spiked heparin samples because using spiked samples often results in therapeutic ranges higher than those calibrated from actual patient samples. The heparin therapeutic range needs to be reevaluated with each new lot number of reagent or change in reagent manufacturer. If there is a clinically significant change in the therapeutic range (e.g., greater than 5–10 seconds), adjustment of the therapeutic range reported by the laboratory is needed. In addition, protocols used throughout the health system should be adjusted as appropriate (Figure 25.5).

Monitoring anticoagulants by the aPTT can be problematic for many reasons and may be reflective of factors independent of the anticoagulant being used. As mentioned previously, results vary depending on the aPTT reagent and lot number. The aPTT can be shortened or prolonged because of deficiency or excess of coagulation factors. In addition, the phospholipids within the assay make it vulnerable to interference from lupus inhibitors. Discordance between anti-Xa activity and aPTT results can occur in a significant number of hospitalized patients on UFH. As seen in Figure 25.6, patients with a goal aPTT measurement may actually have a sub- or supratherapeutic anti-Xa level. Conversely, patients with an aPTT outside the goal range may actually have a therapeutic anti-Xa level. For this reason, many institutions have changed to monitoring UFH according to anti-Xa results; however, consideration of the concordance or discordance with aPTT values in critically ill patients may provide a clearer picture of global coagulation and correlate better with clinical outcomes. In a recent study of 2,321 paired values from 539 patients, 42% of data pairs had a high aPTT value relative to the anti-Xa value. Patients with elevated baseline PT/INR or aPTT often had disproportionate relative prolongation of the aPTT. Patients with at least two consecutive high aPTT to anti-Xa values had increased 21-day major bleeding (9% vs.
3%; p = 0.0316) and 30-day mortality (14% dead vs. 5% dead at 30 days; p = 0.0202) compared with patients with consistently concordant values. The results of this study call for the potential need to evaluate both tests at least initially to identify patients with significantly discordant aPTT and anti-Xa findings to proactively determine whether they may be at risk of bleeding or thrombosis.

**Figure 25.4** Calibrating the goal activated partial thromboplastin time range that corresponds to an anti-Xa activity of 0.3–0.7 for unfractionated heparin.

**Figure 25.5** Creation of goal aPTT targets and titration algorithms according to the correlation between anti-Xa and activated partial thromboplastin time results.
Unfractionated heparin resistance can also be identified by failure to obtain a therapeutic aPTT despite escalating doses of UFH (e.g., greater than 25 units/kg/hour). If this occurs, evaluation of antithrombin III activity may need to be considered. However, the low response to heparin may be because of increased clearance, increased binding to heparin-binding proteins, or increases in acute-phase reactants such as factor VIII or fibrinogen.\(^8\)

The aPTT is the most common test used for monitoring parenteral DTI therapy (e.g., argatroban or bivalirudin). Although the aPTT is used to monitor DTIs, the dose-response is not linear, and the aPTT reaches a ceiling threshold with high concentrations of the drug in plasma. The goal therapeutic aPTT range for parenteral DTIs is not the same as the heparin-calibrated curve by the anti-Xa regression analysis. Many
centers simply use the DTI package insert–recommended aPTT goals and create an individualized goal aPTT range on the basis of the patient’s baseline aPTT (goal aPTT 1.5–3 times baseline aPTT for argatroban or 1.5–2.5 times baseline aPTT for bivalirudin). Alternative options are to create a titration algorithm that is based on the mean of the normal aPTT range (or, in some cases, the upper end of the normal range) to create a standard aPTT goal for all patients. Alternative options are to create a titration algorithm that is based on the mean of the normal aPTT range (or, in some cases, the upper end of the normal range) to create a standard aPTT goal for all patients (Figure 25.7).\footnote{11,12} Given that many critically ill patients do not have a normal aPTT at baseline, this approach may be limited. Laboratories can also create a therapeutic range that is based on spiked normal plasma with known concentrations of each DTI. This may allow for detecting different reagent lot sensitivities to the DTIs. However, the concentration versus aPTT regression line is curvilinear, and little evidence is currently available linking a goal range of DTI plasma concentrations to therapeutic and safety outcomes. Other options include the development of aPTT range using ecarin chromogenic or dilute thrombin time or plasma diluted thrombin time (dTT) assays, but these require a clinical laboratory to perform significant validation steps throughout the process and are more cumbersome than the methods mentioned earlier.

The timing of aPTT monitoring varies between institution, DTI, and organ function and expected time to steady state (extended time to steady state would be expected for argatroban in patients with hepatic impairment and bivalirudin in patients with renal impairment). When developing an aPTT monitoring plan for parenteral DTIs, an aPTT should be monitored within 2–4 hours of initiation or after any dosing change. After this, the aPTT can be monitored every 4–6 hours until at least two consecutive aPTTs are within the goal range. Once this occurs, the frequency can be extended to once daily.\footnote{8,11,12}

\section*{ANTI-Xa MONITORING}

The anti-Xa can be measured using a functional assay to determine anticoagulation intensity for anticoagulants that directly or indirectly affect factor Xa. The test is performed by adding patient plasma to a
reagent factor Xa and measuring factor Xa activity using a substrate that releases a color compound when cleaved. The premise of the assay depends on the fact that the factor Xa activity is proportional to the amount of anticoagulant in the plasma. The most common anti-Xa activity assays currently used are chromogenic because clot-based assays may underestimate activity.
MONITORING
Nursing to titrate argatroban or bivalirudin infusion according to aPTT result using orders and the table below:

- Check aPTT at baseline, 2 hours after initiation, every 4 hours after any dosing change, and then every morning after two consecutive aPTTs in goal.
- Goal aPTT for argatroban and bivalirudin is 50–80 seconds (about 1.5–2.5 times the baseline aPTT). Standard aPTT goal and dosage adjustment will be used unless prescriber fills out “patient-specific aPTT goal” ranges in the table below.

**Figure 25.7** Example of a monitoring and titration algorithm for direct thrombin inhibitor therapy.
Institutions may use a single hybrid anti-Xa curve for UFH and LMWH, or create separate titration curves. Anti-Xa assays are typically calibrated using UFH. It is important to verify that the correct calibrated anti-Xa curve is being used for the anticoagulant being tested. Of note, use of the UFH-derived curve to evaluate LMWH can underestimate the LMWH effect, whereas use of the LMWH curve for measuring UFH can overestimate the UFH effect. Because of these differences in calibration, target anti-Xa levels may vary between laboratories. In addition, the activity of fondaparinux and the direct-acting oral anticoagulants (DOACs) requires a separate anti-Xa calibration before the results can accurately be interpreted.

The anti-Xa goal range was originally established using protamine sulfate titration. Variability in assay performance can occur because of different lots of heparin, the addition of exogenous antithrombin, or variations in the process of creating the standard curve. Antithrombin supplementation or the administration of antithrombin either directly or indirectly (e.g., through the administration of fresh frozen plasma) may result in altered anti-Xa results. Other outside influences listed as having a potential to interfere with the reagent include plasma concentrations greater than 1.5 g/L hemoglobin (0.15 g% or greater plasma free hemoglobin), greater than 288 mg/L conjugated bilirubin (28.8 mg% or greater direct bilirubin), greater than 138 mg/L unconjugated bilirubin (13.8 g% or greater indirect bilirubin), and greater than 6.9 g/L triglycerides (690 mg% or greater triglycerides).

Despite the potential effects of outside influences, the anti-Xa provides a potentially more accurate measurement of UFH therapy. For this reason, many institutions have moved to monitoring UFH by anti-Xa rather than aPTT. The anti-Xa may be preferred to the aPTT for monitoring UFH in patients with suspected heparin resistance, lupus anticoagulant, or antiphospholipid antibodies or when the aPTT results do not appear to correlate with UFH dosing adjustments. In general, anti-Xa monitoring of UFH results in fewer variations in results, reduced testing, fewer dose changes, and more time within the therapeutic range. However, limited data are available regarding the use of anti-
Xa–based titration and clinical outcomes, and as mentioned in the aPTT section within this chapter, discordance between the anti-Xa result and aPTT may be a predictor for risk of bleeding or thrombosis. Monitoring of both the anti-Xa activity and the aPTT may be prudent in certain critically ill patients, such as those with hepatic disease, prolonged baseline clotting time, and significant thrombosis or risk of bleeding and those with factor inhibitors. However, there is little guidance on what clinicians should do if the aPTT and anti-Xa results are discordant. Ultimately, a decision on which assay to use will have to be made according to which laboratory test appears to be correlating best with the patient’s clinical scenario.

The anti-Xa assay can be used similarly to the aPTT when dose adjusting heparin. The anti-Xa activity (heparin level) should be drawn at intervals similar to those recommended for the aPTT (e.g., every 6 hours initially and then at least daily after two consecutive levels in goal are achieved). Heparin nomograms can be used for titrating heparin in a fashion similar to those derived from the aPTT (Figure 25.8).

The anti-Xa assay is the preferred measurement for LMWH; however, monitoring is typically needed only in special populations. Such critical care populations include those with extremes of body weight (e.g., less than 50 kg or more than 150 kg), those with reduced creatinine clearance (e.g., less than 30 mL/minute), pediatric patients, trauma patients, patients with a potential for altered sub-cutaneous absorption (e.g., significant edema), pregnant patients with mechanical valves, or those with unexpected bleeding or thrombosis during therapy. Unlike UFH, where an anti-Xa level can be monitored anytime during the infusion, timing is important when monitoring LMWHs. A peak concentration should be drawn 4 hours after the subcutaneous dose of the LMWH. The goal anti-Xa varies depending on whether once- or twice-daily dosing is used, which LMWH is being administered, treatment versus prophylactic dosing, and the calibration of the assay by the laboratory. For example, the goal concentration for 1 mg/kg of twice-daily enoxaparin may be 0.6–1 IU/mL, and the goal concentration for 200 units/kg of once-daily dalteparin may be 1–2 IU/mL. A peak concentration of 0.2–0.4 IU/mL or a trough
concentration greater than 0.1 IU/mL has been suggested as a target for prophylactic dosing strategies.\textsuperscript{13-15} Of note, a specifically calibrated assay must be used for monitoring fondaparinux. Goal concentrations for fondaparinux are not well established, but anti-Xa peak levels are about 0.39–0.5 mg/L for 2.5-mg/ day doses and about 1.2 mg/L for 7.5-mg/day dosing. Clinicians should consult with their laboratory to determine the therapeutic ranges for the LMWH and dosing strategy used in their patient.

The heparin-calibrated chromogenic anti-Xa assay can also be used to quantitate the newer DOACs.\textsuperscript{16} Currently, calibration kits for rivaroxaban and apixaban are available for research use only. However, hospitals may choose to calibrate their standard anti-Xa assay to measure these DOACs. Of note, the returned values for the DOAC will be significantly higher than those reported for UFH, and dilution of the sample may be required to fit the results within the laboratory’s testing range. Although the PT may provide a quick qualitative assessment of the presence of a DOAC in the patient, the correlation with drug concentration is much higher with the anti-Xa assay than with the PT.\textsuperscript{16} See Figure 25.9 through Figure 25.14.
HEPTEST AND HEPTEST-STAT

The Heptest and Heptest-Stat are clot-based assays that measure heparin or LMWHs and fondaparinux in human plasma, respectively. The assay consists of incubating plasma samples with an equal volume of factor Xa. This mixture is then recalcified by adding a reagent containing optimal concentrations of calcium chloride and brain cephalin in a bovine plasma fraction rich in factor V and fibrinogen. The amount of anticoagulant present in the sample is interpolated from a standard curve of clotting times versus known heparin levels.

The Heptest has a high correlation with the anti-Xa chromogenic...
assay for heparin and LMWH and may more accurately measure the anticoagulant effects of heparins than the aPTT because it is less influenced by high factor VIII levels and lupus anticoagulant.\textsuperscript{17} The Heptest-Stat is most likely to be useful for low-dose heparin monitoring, including dialysis and pediatric patients. The Heptest-Stat has been used for monitoring VTE prophylaxis in pregnant women with and without prosthetic valves because it is unaffected by the hormonal changes common in these patients.\textsuperscript{18}

**ACTIVATED CLOTTING TIME**

The activated clotting time (ACT) is one of the few point-of-care methods used for monitoring anticoagulant therapy in critically ill patients. The ACT is performed by adding an activating agent (e.g., kaolin) to a sample of freshly drawn whole blood and measuring the time to clot formation. The results for time to clot are presented in seconds. The ACT devices use a low- and high-range cassette, which provide different responses depending on the heparin level present. Because the aPTT becomes infinitely prolonged when heparin levels exceed 1 unit/mL, the ACT is typically used to monitor high-dose UFH or DTI therapy during cardiopulmonary bypass or other invasive intravascular procedures such as cardiac angiography and intervention, extracorporeal membrane oxygenation, vascular surgery, or carotid endarterectomy. The ACT is capable of showing a graded response to heparin levels at 1–5 units/mL. Low- and high-dose cartridges are available depending on the dose of anticoagulation and type of procedure being performed.
**Figure 25.9** Correlation between STA liquid heparin hybrid anti-Xa activity and apixaban concentration in spiked samples.

**Figure 25.10** Correlation between STA liquid heparin hybrid anti-Xa activity and rivaroxaban concentration in spiked samples.
The ACT results can be affected by many factors including platelet count, platelet function, lupus anticoagulants, factor deficiencies, blood volume, temperature, and hemodilution (Figure 25.15). The presence of other anticoagulants (e.g., warfarin) or antiplatelet agents (e.g., glycoprotein IIb/IIIa inhibitors) can also increase the ACT.

The optimal goal range for the ACT is not well established, which therefore leads to variability in goals among various procedures and settings. A linear relationship between ACT and thrombosis and bleeding outcomes in percutaneous coronary intervention has not been established; however, increased rates of death, myocardial infarction, and target vessel revascularization have been observed in patients with ACTs of 300 seconds or less.\textsuperscript{19} In patients undergoing cardiopulmonary bypass, a minimal ACT goal may range from greater than 350 to greater than 500 seconds; however, many institutions target a value between 400 and 480 seconds.\textsuperscript{20} The ACT correlates well with heparin level only after the initial bolus of UFH in patients undergoing cardiopulmonary bypass. This correlation decreases significantly during cardiopulmonary bypass, potentially because of hemodilution, hypothermia, and platelet dysfunction (Figure 25.15).\textsuperscript{21}
plasma to the patient sample may improve the correlation.\textsuperscript{22} Reduced heparin sensitivity (e.g., heparin resistance) can also be picked up on if the ACT does not increase as expected with a given UFH dose (\textbf{Figure 25.16}). An arbitrary cut-point of failure to achieve an ACT of greater than 480 seconds despite 500 units/kg of UFH has been a common definition of heparin insensitivity.\textsuperscript{23,24} The clinical importance of identifying heparin resistance is unknown, and considerable debate exists about whether patients should simply be given higher doses of UFH or whether exogenous antithrombin III should be administered.

\section*{ECARIN CLOTTING TIME OR ECARIN CHROMOGENIC ASSAY}

The ecarin clotting time test uses a known quantity of ecarin (thrombin activatable snake venom) and adds this to the plasma of a patient treated with a DTI. Ecarin activates prothrombin through a specific proteolytic cleavage, which produces meizothrombin, a prothrombin-thrombin intermediate that retains the full molecular weight of prothrombin but possesses a low level of procoagulant enzymatic activity. This activity is inhibited by DTIs, but not by heparin. The ecarin clotting time is also unaffected by prior treatment with warfarin or the presence of phospholipid-dependent anticoagulants, such as lupus anticoagulant. Thus, the ecarin clotting time is prolonged in a specific and linear fashion with increasing concentrations of DTIs.

An enhancement of the ecarin clotting time is the ecarin chromogenic assay in which diluted sample is mixed with an excess of purified prothrombin, and the generated meizothrombin is measured with a specific chromogenic substrate. This assay shows no interference from prothrombin or fibrinogen in the sample and is suitable for measuring all DTIs.\textsuperscript{25,26} Unfortunately, this test is not yet FDA approved for use in the United States. Even if the test becomes available, many questions remain regarding the optimal drug concentration and correlation of the ecarin chromogenic assay to patient outcomes.
THROMBIN TIME AND DTT

The thrombin time (TT) measures the conversion of fibrinogen to fibrin, the final step in the clotting pathway. The test measures the time it takes for a clot to form in the plasma of a blood sample containing anticoagulant after an excess of thrombin has been added. It is typically used to diagnose blood coagulation disorders and to assess the effectiveness of fibrinolytic therapy. The TT compares the rate of clot formation with that of a sample of normal pooled plasma. Thrombin is added to the samples of plasma. If the time it takes for the plasma to clot is prolonged, a quantitative (fibrinogen deficiency) or qualitative (dysfunctional fibrinogen) defect is present. Thrombin time can be prolonged by anticoagulants (e.g., heparin or DTIs), fibrin degradation products, and fibrinogen deficiency or abnormality. The assay can be affected by fibrinogen concentrations, with fibrinogen concentrations greater than 600 mg/dL causing as much as a 5%–20% decrease in expected dTT compared with samples with normal fibrinogen values.\(^\text{27}\)

The TT has a high sensitivity to anticoagulants, particularly DTIs.\(^\text{27}\) For example, if used to monitor DTIs, this unmodified TT will provide results above the threshold for the assay (e.g., greater than 200 seconds). Therefore, the assay is typically diluted with pooled normal patient plasma by a 1:4 ratio yielding a dTT. The dTT may provide an alternative to the aPTT for monitoring UFH or DTIs, but because of the availability of other laboratory options for UFH, its use is more common with DTIs.\(^\text{28}\) Potential advantages of the assay compared with the aPTT are avoidance of interference by lupus inhibitors, deficiency in vitamin K–dependent factor levels, or elevated D-dimer concentrations. Although the dTT can be run by automated machines, additional work must be done at individual institutions to dilute the patient samples and calibrate the assay according to DTI plasma concentrations (Figure 25.17). Additional considerations are the appropriateness of choosing the target therapeutic range for the dTT test because the goal therapeutic concentrations for DTIs vary depending on the source. For example, published argatroban goal concentrations equivalent to an aPTT of about 1.5–3 times baseline aPTT have been reported as 0.5–1.5 mcg/mL, 1–2 mcg/mL, and 0.4–1.1 mcg/mL.\(^\text{29-31}\) The
predominance of pharmacokinetic information with bivalirudin is in patients undergoing percutaneous coronary intervention or coronary artery bypass grafting, which uses significantly higher doses and yields concentrations of 1–15 mcg/mL. This range is even less well defined for bivalirudin in patients with heparin-induced thrombocytopenia and is approximated to be anywhere from 0.25 to 1.5 mcg/mL. To account for this, some institutions have decided to truncate the goal range to a mean of the concentrations reported in the literature (e.g., 0.8–1.2 mcg/mL). However, more data are needed linking therapeutic concentrations to clinical outcomes before a specific goal can be recommended. Furthermore, individual ICU patient considerations, treatment goals, and risk-benefit of thrombosis and bleeding should be considered when designing a patient’s therapeutic goal. Use of the test for DTIs should likely be reserved for patients with altered baseline aPTT values (e.g., patients with lupus anticoagulant) or those with an unexpected aPTT response in concordance with usual DTI dosing strategies.

\[ y = 0.0171x + 0.3034 \]
\[ R^2 = 0.992 \]
Factors affecting the activated clotting time result.

Factors prolonging the activated clotting time independent of heparin effects. Low...
coagulation factors, low platelets, and low fibrinogen can all prolong the activated clotting time (ACT). Additional confounders that cause the ACT not to correlate well with heparin levels include hypothermia (less a problem when small sample sizes are used), excess protamine, and the presence of antiphospholipid antibodies (typically found in patients with lupus).\textsuperscript{21}

**PROTHROMBINASE-INDUCED CLOTTING TIME ASSAY**

The prothrombinase-induced clotting time (PiCT) assay is a clotting assay that is sensitive to factor Xa and IIa. The assay adds factor Xa and Russell viper venom to platelet-poor plasma. After incubation, the plasma is recalcified, and the clotting time is determined. The PiCT is a relatively new test that has mainly been studied ex vivo. A mostly linear dose response is observed when evaluating UFH, LMWHs, argatroban, and fondaparinux.\textsuperscript{33} A study comparing the PiCT assay with the ecarin chromogenic and dTT tests for monitoring argatroban, bivalirudin, and dabigatran showed greater variations in results with the PiCT test.\textsuperscript{11} More studies are needed of critically ill patients before recommendations can be made to use the PiCT test in clinical practice.

**HEMOCLOT THROMBIN INHIBITOR ASSAY**

The Hemoclot thrombin inhibitor assay is a chronometric assay used for the quantitative measurement of both parenteral (argatroban) and oral (dabigatran) DTIs. During the Hemoclot thrombin inhibitor test, the patient’s plasma is first diluted with normal pooled human plasma. Clotting is then initiated by adding a constant amount of highly purified human thrombin. The clotting time measured is directly related to the concentration of the DTI in plasma. Preliminary studies have shown a higher correlation between the Hemoclot thrombin inhibitor test and DTI concentrations in plasma than in the aPTT; however, little is known about the use of this test in clinical practice.\textsuperscript{34,35} The test is relatively new in the United States and currently has no calibrators for bivalirudin.

**THROMBIN GENERATION TEST**
Thrombin generation assays measure the ability of a plasma sample to generate thrombin after activation of coagulation with tissue factor or another trigger. Thrombin generation assays also probe the propagation and termination phases. The thrombin generation curve shows and integrates all procoagulant and anticoagulant reactions that regulate the formation and inhibition of thrombin. Currently, there is poor standardization for the assay among institutions, which significantly limits its application in clinical practice.  

**REPTILASE TIME**

Reptilase is an enzyme similar to thrombin. It is different from thrombin because it resists inhibition by heparin through antithrombin. In addition, it is unaffected by DTIs. Reptilase time is useful for detecting abnormalities in fibrinogen and in detecting whether heparin or DTIs are causing a prolongation of the TT.

**THROMBOELASTOGRAPHY**

Thrombelastography (TEG) is a common method of performing point-of-care monitoring of coagulation. It provides clinicians with real-time results of whole blood coagulation status and is applicable at the bedside. More specifically, the TEG device provides graphic representation of the rate of fibrin polymerization, platelet function, and clot strength and stability through in vivo interactions of the coagulation system with platelets and red blood cells at the patient’s actual temperature.
Dose-response graph for initial heparin bolus as measured by the activated clotting time. (A) Before commencing cardiopulmonary bypass (CPB), the relationship of an intravenous heparin bolus and the resulting ACT is relatively linear. This relationship does not continue during CPB. (B) The heparin sensitivity index (HSI) is the dose-response slope. It is calculated by subtracting the baseline ACT measurement from the ACT obtained after the loading dose (both measured in seconds) and dividing that by the loading dose of heparin given (in units per kilogram).^{21}
Thromboelastography was first described in 1948 as a research device to assess global viscoelastic changes in coagulation of a single blood sample. In 1996, thromboelastograph and TEG became registered trademarks of the Haemoscope Corporation (Niles, IL) and now describe the assay performed using Haemoscope instrumentation only. Rotational thromboelastography (ROTEM) also measures the viscoelastic properties of coagulation and differs from TEG in proprietary components and coagulation activators but has similar graphic results.
**PRINCIPLES OF THROMBELASTOGRAPHY**

The TEG/ROTEM devices both assess the viscoelastic physical properties of clotting whole blood, but they do so in a blood sample cup; this negates the high shear forces otherwise found in the vessels of the circulatory system. Because the TEG measures coagulation status under a no-flow (static) state in a blood sample cup (in vitro), it is important to emphasize that the results should be interpreted in context of the clinical scenario.\(^{38}\) The TEG device uses a stationary cylindrical blood sample cup and oscillates through an angle of 4° 45’ with each rotation lasting 10 seconds.\(^{6}\) An immersed pin is suspended in the blood by a torsion wire and is monitored for motion. Torque is generated between the oscillation of the blood sample cup and the pin only after fibrin-platelet bonding has linked the cup and pin together. The graphic output of the rotational movement is related to the magnitude of strength of these fibrin-platelet bonds for the immersed pin. The TEG device may graphically represent robust or weak fibrin-platelet bond interactions depending on the level of coagulation and fibrinolysis the sampled blood is experiencing.\(^{38}\) The ROTEM device uses modified technology compared with the TEG device using an optical detector rather than a torsion wire, and the mechanical oscillation originates from the pin, not the blood sample cup. Furthermore, the ROTEM instrument uses different plastic for the pin and cup that enhances contact activation with the sample; it also is equipped with an automatic pipette device and has proprietary formulas for coagulation activators different from those of the TEG system.\(^{37,38}\)

**Table 25.2** describes the TEG/ROTEM viscoelastic measurements and the variable nomenclature that represent the different stages of
developing and resolving clot. The time until initial fibrin formation is the reaction (R) time (TEG) or clotting time (CT) (ROTEM); the kinetics of fibrin formation and clot development is the kinetic (K) or alpha angle (α) (TEG) or the clot formation time or alpha angle (α) (ROTEM); the strength and stability of the fibrin clot is the maximum amplitude (MA) (TEG) or maximum clot firmness (MCF) (ROTEM) and clot lysis (CL) (TEG) or clot lysis (LY) (ROTEM).

**USE OF TEG FOR MONITORING ANTICOAGULANT THERAPY**

Thromboelastography produces a tracing that depicts parameters measured throughout the life span of a clot (Figure 25.18). Alterations because of anticoagulation therapy or coagulopathies result in alteration of the tracing. Interpretation of the tracing (Figure 25.19) or output results (Table 25.3) can provide insight into the contributions of anticoagulant therapy versus those of other contributors to alterations in the clotting cascade that may be present in critically ill patients on anticoagulation.

TEG (thromboelastography): N = normal values for kaolin activated TEG in native whole blood (WB) or citrated and recalcified blood samples (Cit) (Haemoscope Corp.) or ROTEM using contact (partial thromboplastin phospholipids, in-TEM), tissue factor (ex-TEM), and tissue factor plus platelet inhibitor cytochalasin D (fib-TEM) activated citrated and recalcified blood samples. Reference value depends on reference population, blood sampling technique, and other re-analytic factors and coagulation activator.

Thromboelastography can be used to evaluate the effect of heparin, either exogenous or endogenous, by placing the sample into cups coated with heparinase. This enzyme, unlike protamine, will antagonize the effects of heparin without affecting TEG/ROTEM variables. The heparinase-coated cup samples can be analyzed in parallel with non-coated cup samples to determine whether heparin is still present (e.g., in the case of protamine reversal) or to monitor coagulation in the presence of full-dose heparin therapy. The difference in R time between the simultaneously performed TEG with and without heparinase provides a linear relationship between heparin level and R time and allows for the determination of heparin dosing in patients. The test times of TEG and ROTEM are typically 20 minutes or less, which offers a convenient point-of-care option if the machine is located near the patient. The downside to the TEG for monitoring heparin is the lack of clinical outcomes associated with the results provided. This makes it difficult to establish the goal R time and an appropriate...
recommendation for dosage adjustment that is based on the result. Although the use of the TEG for monitoring heparin therapy is a plausible option, it still becomes a distant alternative to the aPTT and anti-Xa assay for routine monitoring of heparin therapy.

In addition to monitoring UFH, TEG can detect the anticoagulant effects of LMWHs. Thromboelastography has been compared with anti-Xa activity using a variety of end points including R time, α angle, and maximum amplitude. Most, but not all, studies have shown a good correlation between the anti-Xa results and TEG R time or change in R time.\textsuperscript{41-43} The goal R time or change in R time is unknown, but a study of coronary care unit patients showed that every 10% increase in milligram per kilogram dose of enoxaparin resulted in an increase in R time of 2.7 (95% confidence interval, 0.6–4.7).\textsuperscript{41} Almost all patients had an R time of more than 8 minutes when peak levels were drawn 4 hours after a 1-mg/kg subcutaneous enoxaparin dose. Most studies to date are too small to correlate TEG results to clinical outcomes in patients on LMWH. A study of 87 trauma and general surgery patients used TEG-guided enoxaparin dosing to increase the R time by 1–2 minutes. They compared this TEG-adjusted regimen with a standard 30-mg twice-daily regimen. Thromboelastography-guided therapy resulted in increased LMWH dosing and anti-Xa levels, but no decrease in VTE.\textsuperscript{44} Therefore, at this time, TEG may be considered an additional tool for monitoring LMWH when the anti-Xa assay is not readily available or there is a question about the accuracy of the reported results.
Figure 25.18  Thromboelastography tracing and measured parameters.

Normal viscoelastic tracing of TEG/ROTEM. Upper side: Thromboelastography (TEG) tracing: $\alpha$ = slope between R and K; CL = clot lysis; K time = kinetic time; MA = maximum amplitude; MA$_{60}$ = maximum amplitude 60 min after initial maximum amplitude; R = reaction time. Lower side: Rotation thromboelastography (ROTEM) tracing: $\alpha$ = slope of tangent at 2 mm amplitude; CFT = clot formation time; CT = clotting time; LY = lysis; MCF = maximum clot formation firmness.
Thromboelastography assays using ecarin can be used as an alternative method to monitor DTIs.\textsuperscript{45-47} Adding ecarin to the TEG initiates coagulation, and the effect of bivalirudin is measured by the change in R time. Compared with the ACT, correlation of the ecarin TEG with bivalirudin concentration was significantly higher with the TEG ($r^2 = 0.75$) versus the ACT ($r^2 = 0.31$) $[p<0.001]$.\textsuperscript{46} For a range of bivalirudin concentrations from 2 to 11 mcg/mL, the R time increased from $144 \pm 109$ seconds to $557 \pm 105$ seconds in a linear fashion. The TEG may provide an alternative option to the aPTT and dTT, but
routine use cannot be recommended at this time.

Thromboelastography can also be used for detecting the newer DOACs. In patients taking dabigatran, apixaban, rivaroxaban, or edoxaban, the kaolin test reaction time (R time) and the time to maximum rate of thrombus generation are elevated in a dose proportional response relationship. The RapidTEG reagent also appears effective at detecting the DOACs. This allows laboratories to create a dose-response curve to determine the amount of drug in the system. The clinical utility of TEG for monitoring DOACs requires further elucidation, but it may be useful in patients undergoing emergency procedures or those requiring anticoagulation reversal while taking a DOAC.

Thromboelastography platelet mapping can be used to quantify the response to antiplatelet therapy including both P2Y\textsubscript{12} inhibitors and IIB/IIIA inhibitors. The effects of platelet inhibitors can be observed in the parameters measured by TEG with the standard kaolin activator, with the MA being the predominant component to evaluate. Modification of the TEG assay using reptilase and factor XIIIa is used to generate a whole blood crosslinked clot in the absence of thrombin generation or platelet activation. This increases the sensitivity of the TEG for measuring platelet contribution to shear elasticity of the clot and allows for measurement of a larger range of antiplatelet activity. This modification also permits convenient monitoring of patients receiving antiplatelet therapy during interventional procedures. Further studies are needed to establish the goal target MA range and the ability of the TEG to predict patient outcomes.

Overall, the TEG or ROTEM tests have the potential to monitor all current anticoagulant and antiplatelet therapies. This, plus the ability to differentiate the contribution of anticoagulants and/or antiplatelet agents versus endogenous factors affecting the coagulation pathway, makes it a very intriguing option to use in critically ill patients. Despite our increasing familiarity and potential applications of the TEG/ROTEM, the paucity of clinical data and the lack of routine availability of the test in many hospitals currently limit its use.
D-DIMER

Plasmin cleaves fibrin-releasing fibrin degradation products. D-dimer is one of the main fibrin degradation products, which consists of two D domains from adjacent fibrin monomers that have been crosslinked by activated factor XIII. An elevated plasma D-dimer indicates recent or ongoing intravascular blood coagulation. A D-dimer will be detectable at concentrations greater than 500 ng/mL in almost all patients with VTE. Therefore, a D-dimer is often used to rule out thrombosis and has a greater than 96% negative predictive value. However, how to evaluate elevated D-dimer concentrations is more controversial. Critically ill patients may have many reasons to have an elevated D-dimer (Table 25.4); therefore, it is unlikely that a single D-dimer would be helpful in monitoring anticoagulation therapy. It is conceivable that following trends in D-dimer could provide evidence of the effectiveness of the anticoagulant to prevent clot formation. In patients on extracorporeal membrane oxygenation therapy, an increasing D-dimer may be a marker for early diagnosis of thrombus formation and dysfunction of heparin-coated membrane oxygenators. It is possible that monitoring D-dimer changes on a daily basis will provide insight into the effectiveness of anticoagulation for other indications, but more research is needed before this can routinely be recommended.

PLATELET REACTIVITY TESTS

Platelet function testing can now be conducted and applied at the bedside to help determine the degree of platelet reactivity and identify whether an adjustment to therapy is warranted to reduce the risks of both ischemic and bleeding complications. Specific tests are available for P2Y12 inhibitors (e.g., VerifyNow PRU test), aspirin (e.g., VerifyNow aspirin test), and IIb/IIIa inhibitors (e.g., VerifyNow IIb/IIIa test). Each test is based on the ability of activated platelets to bind fibrinogen. Fibrinogen-coated microparticles aggregate in whole blood in proportion to the number of expressed platelet GP IIb/IIIa receptors. Light transmittance increases as activated platelets bind and aggregate fibrinogen-coated beads. The instrument measures this change in
optical signal caused by aggregation and reports results in platelet aggregation units (platelet activity units, IIb/IIIa test), P2Y$_{12}$ reaction units (platelet reactivity units, P2Y$_{12}$ inhibitors), or aspirin reactivity units. Most tests take about 10 minutes to produce results.

The need for platelet monitoring is based on the premise that it will improve patient outcomes. However, data analyses to date are mixed regarding any clinical outcome improvements.\textsuperscript{60-63} A recent randomized multicenter study of 2,440 patients scheduled for coronary stenting was unable to show any significant improvements in clinical outcomes with platelet function monitoring with dose adjustment compared with standard antiplatelet therapy without monitoring.\textsuperscript{61} Given the lack of a clear benefit in most patients, point-of-care monitoring of platelet activity should likely be reserved for patients with significant drug interactions with their antiplatelet medications, those with concerns about oral antiplatelet absorption, and those with a significant risk of bleeding.

FUTURE DIRECTIONS IN LABORATORY ANTICOAGULATION TESTING

Despite the many tests available and the vast experience with antithrombotic agents, bleeding and thrombosis are still substantial contributors to morbidity and mortality in the ICU. The problem with many anticoagulant laboratory tests is their evaluation of only a portion of the coagulation process and their susceptibility to outside influences. Many tests may be a good surrogate for an anticoagulant’s contribution to a specific portion of thrombus generation, but they may lead to a lack of understanding of the entire hemostatic process that places a patient at risk of unintended outcomes. Many believe that global assays of hemostasis (e.g., TEG) are more reflective of likely clinical outcomes such as VTE, bleeding, length of stay, and mortality. However, their lack of standardization and limited data showing their sensitivity and specificity for predicting clinically important outcomes preclude their use as a standard of care for most ICU patients. Novel global assays in development build on currently available tests and include thrombin and plasmin generation, thrombodynamics, and flow perfusion chambers. Despite the potential advantages of these new
options, most of these tests are in their infancy. Large patient cohorts will be necessary to determine whether they offer any clinically meaningful advantage over current laboratory options. Given that the data generated will have to show both a statistically and a clinically meaningful difference, clinicians are likely to have to choose a monitoring strategy from the currently available laboratory tests for the near future.

**CONCLUSION**

Routine anticoagulant laboratory tests, including the PT, aPTT, and anti-Xa, are commonly ordered to assess clotting function in critically ill patients. Many variables commonly present in critically ill patients must be considered when interpreting the results of coagulation laboratory tests. Newer laboratory tests are available that may be more specific for monitoring certain anticoagulants; however, data correlating results to clinical outcomes are limited. Many assays are performed on several platforms using different reagents between institutions, making standardization difficult to accomplish. Critical care clinicians should have a close working relationship with the anticoagulation laboratory and hematologists to ensure appropriate use of coagulation testing and interpretation.

LEARNING OBJECTIVES

1. Describe the basic etiology, common causes, and prognosis of acute kidney injury (AKI).
2. Differentiate prerenal azotemia, intrinsic AKI, and postrenal causes of AKI.
3. Explain how laboratory tests are used to differentiate between various types of AKI.
4. Discuss approaches to prevent and treat AKI.
5. Explain measures the critical care pharmacist may use to predict, prevent, and manage drug-induced AKI.

ABBREVIATIONS IN THIS CHAPTER

ACEI  Angiotensin-converting enzyme inhibitor
AKI  Acute kidney injury
AKIN  Acute Kidney Injury Network
ARB  Angiotensin receptor blocker
INTRODUCTION

Monitoring kidney function and hemodynamics is a mainstay of intensive care medicine. Acute kidney injury (AKI), previously called acute renal failure, is characterized by a rapid decline in glomerular filtration rate (GFR) and excretory function in the kidneys. The traditional assumptions about acute changes in kidney function have been challenged within the past decade, with a renewed focus on earlier, mild injury associated with adverse clinical outcomes, particularly in the critically ill population. This chapter will review the most recent approaches to preventing, defining, staging, and managing AKI with an emphasis on patient care.

Incidence and Prognosis

Acute kidney injury reportedly affects almost 500 people per 1 million each year, including 5% of all hospitalized patients, with around 40% of these requiring acute renal replacement therapy (RRT). The timeline for developing AKI after an acute insult ranges from hours to
days or weeks and has been reported to occur in up to 20% of hospital admissions. The reported incidence of AKI in post-surgical populations ranges from 0.8% (minor surgery) to 36.7% (major surgery), with mortality (90 day and 5 year) increasing 2- to 3-fold in the presence of AKI. The incidence of AKI in intensive care unit (ICU) patients is even higher, approaching 50% in patients with early AKI.

The prognosis of patients with AKI is associated with the degree of reduced urine output and the duration and severity of AKI. For example, it is widely reported that a urine output of less than 0.5 mL/kg/hour for 6 hours is associated with increased mortality even in the absence of changes in serum creatinine. However, lower thresholds for urine output have been associated with worse outcomes. In a critical care cohort study, Ralib et al. reported that a urine output below 0.3 mL/kg/hour for 6 hours was associated with a marked increase in mortality. The length of time serum creatinine remains elevated, or the duration of AKI, has also been associated with worse outcomes. Long-term survival was associated with the duration of AKI in patients post-cardiac surgery and in patients with diabetes non-cardiac surgery, where the mortality for patients with 3–6 days of initial AKI was greater than 2 or fewer days of more advanced stages of AKI.

**Etiology**

Acute kidney injury is highly preventable and usually reversible, with recovery taking days to weeks. If prolonged, AKI can progress to end-stage kidney disease requiring chronic RRT. Thus, identifying risk factors for AKI (see Table 26.1) is critical to prevent it from developing.

According to NCEPOD (the UK National Confidential Enquiry into Patient Outcome and Death), around 20%–30% of all AKI events are predictable and avoidable. In reviewing more than 1,500 AKI-related deaths, this expert advisory group found that only 50% of patients receiving care for AKI met acceptable medical practice standards (defined as “good”). A likely contributor to inadequate care for patients with AKI is failure to recognize and manage the condition. For
example, azotemia, defined as a nonspecific elevation in serum urea nitrogen concentration, is common in patients with gastrointestinal bleeding, severe catabolism, oliguria, intravascular volume depletion, and after administering drugs that alter renal hemodynamics. Other confounding factors include nonspecific elevations in serum creatinine, as noted in patients with increased muscle mass, associated with increased dietary protein intake, or after severe muscle injury or rhabdomyolysis. Thus, a complete clinical assessment is needed before an accurate diagnosis of AKI can be made. Regardless of the etiology of AKI, both ischemic injury and directly toxic injury to the kidney can ultimately lead to AKI, including acute tubular necrosis (ATN). Acute kidney injury in the ICU population is often complicated by several organ system failures occurring simultaneously. These critically ill patients may be receiving pharmacologic and life-support treatments, including RRT to maintain adequate homeostasis.

PATHOPHYSIOLOGY

The two fundamental mechanisms contributing to AKI are hypoxia and cellular injury. The kidneys receive almost 20% of cardiac output to meet the high tissue oxygen demands. The tubular regions in the loop of Henle have the highest oxygen extraction ratio (relative to O$_2$ delivery) of any cell in the human body, with almost 80% of delivered oxygen being used.$^{11}$ Most of the oxygen consumption is related to ATP-dependent sodium transporters that drive the major fluid homeostasis mechanism of the body. This activity is coupled with GFR, where increased ultrafiltrate delivery leads to higher sodium reabsorption and greater oxygen consumption. The three primary mechanisms of AKI are conventionally classified according to relative hemodynamics and vascular anatomy.

Prerenal Azotemia

Azotemia classified as “prerenal” indicates that an acute decrease in GFR has occurred in an otherwise normal kidney, in response to
hypovolemia or hypoperfusion. As an initial response to hypoperfusion, blood flow is redistributed to the hypoxic regions of the kidney (medulla). Renal ischemia and tissue hypoperfusion, if present for a prolonged duration, can ultimately lead to loss of renal cellular integrity and tissue necrosis. In severe ischemia, tubular sodium reabsorption is compromised, leading to urinary sodium loss and activation of the renin-angiotensin-aldosterone system (RAAS). This leads to heightened afferent arteriolar tone and a decrease in GFR. Without this RAAS-mediated negative feedback mechanism, the GFR would remain unchanged, and severe dehydration and death would rapidly ensue. The reduced GFR and urine output (oliguria) in the face of AKI serves as a mechanism that sacrifices GFR to maintain life. This functional feedback loop is often called “acute renal success” as opposed to renal failure.

ACEI = angiotensin-converting enzyme inhibitor; AKI = acute kidney injury; ARB = angiotensin receptor blocker.
Intrarenal (Intrinsic) AKI

Intrinsic renal causes are important sources of AKI and are usually categorized by the mechanism of direct injury that typically occurs in each condition. The most common forms of intrinsic AKI likely to be seen in ICU settings include sepsis, ATN, ischemia/vascular, and endogenous nephrotoxins.

Sepsis

Sepsis is the most common form of AKI occurring in the ICU population (greater than 30%). The exact mechanism is not fully understood, but it likely involves a complex interplay between initial reduction in vascular resistance, hypoperfusion, ischemia/reperfusion, and apoptosis.12,13

Acute Tubular Necrosis

Acute tubular necrosis is the leading cause of non-sepsis AKI in the ICU. Because of the close association of ATN with pre-renal azotemia, it is important to distinguish the two forms using clinical signs, medical history, and laboratory criteria (see Table 26.2). The time course of ATN is often described by a three-part series of events: initiation, maintenance, and recovery. The initiation phase is characterized by an acute decline in GFR, followed by a rapid rise in serum creatinine and blood urea nitrogen (BUN) concentrations. The maintenance phase is characterized by a sustained reduction in GFR, continuing for up to 2 weeks. Because GFR is severely compromised during this phase, serum creatinine and BUN continue to rise. During the recovery phase, tubular function is restored, leading to an increase in urine output and a return of the BUN and serum creatinine concentrations to their pre-injury levels. The extent of tubule cell damage and nephrotoxicity in ATN depends on the kidneys’ capacity to recover from the initial insult, intrarenal vasoconstriction, and any intratubular obstruction.

Ischemia/Vascular

Ischemic ATN is often closely related to prerenal azotemia, given that
both conditions are caused by similar insults. Ischemic ATN occurs after prolonged hypoperfusion, where the initial autoregulatory responses in the kidney are overwhelmed. Here, severe hypoperfusion leads to cell injury and cell death.

**Endogenous Nephrotoxins**

Conditions associated with traumatic injury or muscle toxicity can lead to rhabdomyolysis-induced AKI. Extensive hemolysis caused by severe blood transfusion reactions can lead to myoglobin-induced AKI. Acute crystal-induced nephropathy is another endogenous form of AKI, caused by myeloablative cancer treatments associated with high cell turnover (and release of uric acid crystals), but it may also be caused by acute ingestions of ethylene glycol or high-dose vitamin C.

**Exogenous Nephrotoxins**

Many nephrotoxic drugs that are associated with ATN are commonly used in the ICU. Individual nephrotoxic drugs are rarely the sole cause of AKI, unless given in high doses over a long period. Nephrotoxic drugs used in high-risk patients with preexisting conditions such as chronic kidney disease, sepsis, dehydration, or hypotension, or the use of vasopressors, can increase the likelihood of AKI in the ICU.

Examples of drug-induced ATN include the following:

- Aminoglycoside-related toxicity occurs in 10%–30% of patients receiving aminoglycosides, even when serum drug concentrations are within the typical therapeutic range. This is the result of direct toxicity in proximal tubular cells, where uptake is mediated by megalin receptors.\(^\text{14}\)

- Amphotericin B nephrotoxicity is often dose-related, where risk is related to the maximum daily dose (greater than 3 g) and therapy duration. The mechanism is likely related to the combined effects of sterol binding in cell membranes and direct vasoconstriction. The increased membrane permeability can lead to the renal wasting of electrolytes, such as
potassium and magnesium, as well as a back-leak of hydrogen ions in the collecting duct, causing distal renal tubular acidosis. Direct vasoconstriction at the afferent arteriole can further contribute to acute changes in GFR and alterations in the tubuloglomerular feedback mechanism.

- Radiographic contrast media can cause contrast-induced nephropathy or radiocontrast nephropathy. These agents cause renal medullary vasoconstriction, decreased renal blood flow, and direct tubular toxicity.\(^{15}\) Radiocontrast nephropathy is associated with several risk factors, including preexisting chronic kidney disease, diabetic nephropathy, heart failure, volume depletion and drugs (i.e., diuretics, nonsteroidal anti-inflammatory drugs [NSAIDs], angiotensin-converting enzyme inhibitors [ACEIs], and angiotensin receptor blockers [ARBs]).

- Nonsteroidal anti-inflammatory drugs can have adverse renal effects that are explained by two distinct pathological processes. The first mechanism of AKI is the result of reduced renal plasma flow caused by a decrease in prostaglandin synthesis, which regulates vasodilation at the glomerular level. Nonsteroidal anti-inflammatory drugs block the compensatory vasodilation response of renal prostaglandins, leading to unopposed vasoconstriction. A second mechanism of AKI is an acute allergic reaction, also known as acute interstitial nephritis. This typically occurs after short-term exposure (less than 7 days) and is characterized by the presence of an inflammatory cell infiltrate in the interstitium of the kidney.

- Calcineurin inhibitors (such as cyclosporin and tacrolimus) often cause acutely severe afferent arteriolar vasoconstriction that impairs glomerular blood flow, leading to decreased GFR. Chronic exposure to these drugs can lead to tubulointerstitial fibrosis, further increasing the risk of AKI when combined with other risk factors, including vasopressors
such as norepinephrine, which are commonly used in ICU settings.

### Postrenal AKI

Postrenal AKI is often caused by an obstruction in the urinary tract downstream from the kidneys, disrupting normal urine outflow. It occurs less often than intrinsic AKI or ATN in ICU settings. Conditions that may lead to postrenal AKI include kidney stones, an enlarged prostate, and neurological conditions leading to incomplete bladder emptying. For example, urinary calculi can be caused by metabolic abnormalities induced by loop diuretics, carbonic anhydrase inhibitors, and laxatives or supersaturation/crystallization with ciprofloxacin, triamterene, and sulfonamide antibiotics. In most cases, normal kidney function is regained if the etiology is identified and corrected promptly.

**DISEASE ASSESSMENT**
History and Physical Examination

A detailed and accurate medical history is critical for understanding the cause(s) of AKI in a given patient. This information is needed to distinguish acute from chronic kidney disease, where symptoms of fatigue, weight loss, anorexia, and pruritus are more common. Findings in the medical history that may predispose an individual to AKI include significant fluid or blood loss (i.e., gastroenteritis, recent surgery), trauma, and exposure to nephrotoxic drugs or heavy metals (mercury, lead, cadmium) that are considered an occupational hazard for welders and miners. Certain preexisting conditions can place patients at an elevated risk of developing AKI, including hypertension, chronic heart failure, diabetes, and autoimmune disorders.

The physical examination may provide evidence of intravascular hypovolemia depending on cardiovascular signs (heart rate, blood pressure) and peripheral edema. The presence of skin lesions may indicate trauma or acute allergic/immune reactions. Abdominal examination may help identify bladder obstruction caused by cancer or an enlarged prostate.

Estimating urine output for the past 3–5 days together with recent hourly fluid intake and output can yield important information about the time of onset and severity of AKI. Oliguria, defined as a urine output less than 400 mL/day, commonly occurs in prerenal and intrinsic AKI, whereas abrupt anuria (less than 50 mL/day) suggests acute urinary obstruction. A slower rate of urine output decline may indicate urethral or bladder outlet obstruction related to prostate hypertrophy.

Serum and Urinary Measures

The criteria most widely used to define AKI are based on (1) rate of rise of serum creatinine and (2) urine output. Until recently, there were no clear guidelines, definitions, or terminology related to AKI, making it difficult to directly compare ICU populations and outcomes in clinical studies. In 2004, the RIFLE approach to categorizing and staging AKI according to risk, injury, failure, loss of kidney function, and end-stage kidney disease was introduced by the ADQI (Acute Dialysis Quality
Initiative) to grade the severity of AKI in the ICU. In 2007, a set of uniform standards for describing and classifying AKI was proposed by the Acute Kidney Injury Network (AKIN). In 2012, a third set of criteria was introduced by the Kidney Disease Improving Global Outcomes (KDIGO) group that incorporates parts of both the RIFLE and the AKIN definitions. A comparison of these approaches is shown in Table 26.3.

The AKIN criteria include a shorter time interval for the rise of serum creatinine (within 48 hours) and include an absolute increase in serum creatinine of 0.3 mg/dL or greater or 50% or greater from baseline. Both RIFLE and AKIN criteria include a reduction in urine output of less than 0.5 mL/kg per hour for more than 6 hours. The KDIGO group further simplified the approach to include a basic definition of AKI, together with severity criteria (similar to AKIN), to provide a single definition that could be applied to practice, research, and public health.

Cystatin C is another surrogate marker used to detect acute changes in kidney function. It has been suggested that the rise in serum cystatin C from baseline occurs earlier than for serum creatinine and is a better early indicator of AKI. Herget-Rosenthal et al. reported that an increase in cystatin C of 50% occurred almost 2 days earlier than a similar rise in serum creatinine. Nejat et al. studied more than 400 ICU patients and reported that changes in urinary cystatin C were detected earlier than for creatinine in patients with AKI, and urinary cystatin C was independently associated with AKI, sepsis, and death within 30 days.

In addition to measuring urine output and classifying staging AKI according to the criteria given previously, measuring the fractional excretion of sodium (FENa) provides an index of the percentage of filtered sodium excreted in the urine that can be used to distinguish prerenal from intrarenal (ATN) causes of AKI (Table 26.1). This nonspecific index of tubular function should not be used alone to evaluate AKI because many other conditions can alter FENa values, including renal salt wasting and diuretic therapy. The FENa is included as part of the comprehensive evaluation of AKI, including medical history, clinical and laboratory evaluation, and urine microscopy.

<sup>a</sup>Within the past 7 days.
<sup>b</sup>Recommended to use MDRD (Modification of Diet in Renal Disease) with estimated GFR of 75–100 mL/minute/1.73m² to estimate baseline creatinine when missing.
<sup>c</sup>Stage 3 also includes any patients with at least stage 1 AKI requiring RRT (renal replacement therapy).

AKIN = Acute Kidney Injury Network; KDIGO = Kidney Disease Improving Global Outcomes; RIFLE = risk, injury, failure, loss of kidney function, and end-stage kidney disease.

Calculating FENa requires measuring the filtered sodium load, which is the product of the creatinine clearance [urine creatinine (UCr) × urine volume (V) divided by serum creatinine (SCr)] and the serum sodium
concentration (SNa). The urinary sodium excretion is equal to the product of the urine sodium concentration (UNa) and the urine volume (V).

This results in the following equation:

$$\text{FENa} \, (\%) = \frac{(\text{UNa} \times \text{SCr} \times 100)}{(\text{SNa} \times \text{UCr})}$$

Although no definitive tests predict AKI, measuring urine output in response to a diuretic challenge has been proposed. For example, a furosemide stress test, consisting of a single dose of furosemide 1 mg/kg in naive patients or 1.5 mg/kg in previously exposed patients, in early AKI (defined as AKIN stage I or II) significantly predicts the patients who will progress to a higher AKI stage. After receiving the furosemide dose, patients were significantly more likely to progress if their subsequent urine output in 2 hours was less than 200 mL (100 mL/hour). The sensitivity and specificity of this test are 87.1% and 84.1%, respectively. Adding other renal biomarkers did not improve the predictive quality of the test.

**Urine Microscopy**

Urine microscopy is readily available and inexpensive and is an important part of the differential diagnosis of AKI. Evaluating the urinary sediment is most useful to distinguish between ATN and prerenal AKI. Urinary microscopy in patients with ATN often reveals renal tubular epithelial cells, cellular casts, granular casts, and muddy brown or mixed cellular casts. In a study of 267 consecutive patients with AKI, a urinary sediment scoring system was a strong predictor of ATN. In the absence of pyelonephritis, the presence of leukocytes, red blood cells (RBCs), and white blood cell (WBC) casts in the urine of patients with AKI can indicate drug-induced acute interstitial nephritis. In contrast, patients with prerenal AKI may have no abnormal findings on microscopy, or occasional hyaline casts.
Renal Imaging and Biopsy Studies

Renal ultrasonography is particularly important for identifying postrenal causes of AKI. For example, the presence of residual postvoiding urine volumes greater than 100 mL can indicate a urine outflow obstruction. Other extrarenal causes of obstruction, such as tumors, can be detected using computed tomography or magnetic resonance imaging. Kidney biopsies are usually reserved for when pre- and postrenal causes of AKI have been excluded and the cause of intrinsic renal injury is unclear. Renal biopsy can be used to confirm acute glomerular and interstitial nephritis (acute interstitial nephritis) that may be related to drug-induced AKI.

Novel Biomarkers

Many novel urinary protein biomarkers have been shown to predict the occurrence and severity of AKI in ICU settings. Haase et al. compiled the results of several studies and found that neutrophil gelatinase-associated lipocalin (NGAL), across different time points, predicted the need for dialysis and death.23 Similarly, Koyner et al. reported that urine NGAL, measured post-cardiac surgery, was a strong predictor of stage 3 AKI and that preoperative urine KIM-1 (kidney injury molecule 1) levels were less predictive.24 Parikh et al. reported that urine IL-18 (inter-leukin-18) was significantly associated with mortality in a subgroup of ICU patients within the ARDS (Acute Respiratory Distress Syndrome) Network trial.25 More recent studies have evaluated novel combinations of biomarkers for their ability to predict AKI. Prowle et al. studied a group of 93 high-risk patients undergoing cardiopulmonary bypass together with combinations of biomarkers to predict RIFLE-R (see Table 26.3) within 5 days after surgery.26 Of the 25 patients who developed AKI, the ratio of urinary NGAL to creatinine measurement postoperatively, followed by urinary hepcidin to creatinine at 24 hours, best identified the patients in the high-, intermediate-, and low-risk AKI groups. In 2013, a combination test was introduced that measures urinary tissue inhibitor of metalloproteinase 2 (TIMP-2) and urinary insulin-like growth factor binding protein 7 (IGFBP-7). The rationale for
studying these two biomarkers is that they are both involved in the G1 cell cycle arrest of renal tubular cells during the early period of cell injury. Derivation and validation of the “TIMP-2 × IGFBP-7” biomarker algorithm in more than 500 patients accurately predicted AKI after cardiac surgery in high-risk patients, resulting in the FDA approval of NephroCheck (Astute Medical, San Diego, CA) as a urinary diagnostic device for AKI in September 2014.

PREVENTION AND TREATMENT

General Approaches

Because of limited treatment options, preventing AKI is essential. Patients at risk of AKI should be identified early, with steps taken to avoid potential renal insults (see Table 26.4). Patient characteristics associated with a greater risk of AKI are included in Table 26.1. Once high-risk patients are identified, instituting general measures lessens the occurrence of AKI. These measures include maintaining appropriate fluid status and, when possible, avoiding diuretics; maintaining adequate blood pressure; and minimizing the use of potential nephrotoxins, including drugs.

Loop diuretics are used in many patients with AKI to either treat or prevent renal failure. Because data regarding the use of loop diuretics in AKI are usually from observational or small clinical trials, often with conflicting results, several meta-analyses have clarified their role. These meta-analyses conclude that loop diuretics have little to no impact on the outcome of AKI. Whether loop diuretics were used to prevent renal deterioration or treat AKI, there was no effect on mortality or the requirement for RRT. The results were mixed regarding number of dialysis sessions and urine output, with one analysis concluding that loop diuretics shorten the duration of RRT and increase urine output, and the other showing no difference. One of the analyses showed a significantly greater incidence of ototoxicity in the loop diuretic group. Loop diuretics also have not proven beneficial in renal recovery after the completion of AKI-related RRT. Overall, using loop
diuretics in AKI remains controversial. There are no definitive trials of critically ill patients, and at this time, the benefit or harm of loop diuretics in AKI is unsubstantiated. The soon-to-be-published SPARK (Furosemide in Early Acute Kidney Injury) study may provide more definitive guidance.34

Hypovolemia

Hypovolemia and volume depletion are significant risk factors for AKI.35 Although no clinical trials substantiate the use of fluids in preventing and treating AKI, their importance in this setting is well accepted. In addition, no large randomized controlled trials analyze the amount of fluid that should be administered to prevent or treat AKI. In the large trials that have compared colloids (e.g., albumin, hetastarches) with crystalloids (e.g., 0.9% saline, lactated Ringer solution) and chloride-liberal with chloride-restricted fluids, the amount of fluid given was at the discretion of the treating clinician.

Many trials have compared colloids with crystalloids for volume depletion in ICU patients. The SAFE (Saline versus Albumin Fluid Evaluation) trial compared the administration of albumin with that of crystalloids (normal saline) in patients who required fluid administration to maintain intravascular volume.36 Although the number of patients who subsequently developed AKI was not specifically delineated in the trial, there were no differences in the number of patients with new single or multiorgan failure. Another study that looked at adding albumin to crystalloid resuscitation in patients with septic shock found similar results.37 Patients received albumin infusions on a daily basis for 28 days, and crystalloids were given according to sepsis guidelines and at the discretion of the clinician. No differences existed in the number of patients who developed AKI or required RRT at 28 days. The CRISTAL (Colloids versus Crystalloids for the Resuscitation of the Critically Ill) trial compared crystalloids with several different colloids (albumin, gelatins, dextrans, hydroxyethyl starches) in patients with hypovolemic shock.38 Results showed no difference in the percentage of patients requiring RRT within 7 or 28 days. Of interest, using hydroxyethyl
starches for resuscitation in this trial did not increase the requirement for RRT as it had in other trials. In fact, a meta-analysis has shown that the use of hydroxyethyl starches for resuscitation increases the risk of AKI and the need for RRT. These data suggest that other than hydroxyethyl starches, which may increase the risk of AKI, the choice of resuscitation fluid, colloid or crystalloid, does not affect the subsequent development of AKI.

Early goal-directed therapy in sepsis is designed to administer fluids to achieve a central venous pressure of 8–12 mm Hg; mean arterial pressure of 65 mm Hg or greater; urine output of 0.5 mL/kg/hour or greater; superior vena cava oxygenation saturation (Scvo$_2$) or mixed venous oxygen saturation (Svo$_2$) of 70% or 65%, respectively; and normalization of lactate concentrations. The results of the original trial showing mortality benefits with goal-directed therapy did not specifically evaluate the benefits related to AKI. However, several organ functioning scores were improved with the therapy. Subsequent trials evaluating the impact of early goal-directed therapy in sepsis did not find any benefit in the fluid strategy for either mortality or AKI. The number of patients requiring RRT and the duration of RRT were not statistically different between groups. There is also concern that fluid accumulation, which may occur in early goal-directed therapy in patients who are volume depleted or hypotensive, may actually increase the risk of AKI. In this trial, patients with fluid overload had greater mortality at 30 days and less recovery of renal function after AKI. In the FACTT study (Fluids and Catheters Treatment Trial), which evaluated conservative versus liberal fluid management of patients with acute lung injury, there was no difference in the incidence of AKI in the two fluid management groups.

- Avoid diuretics
- Maintain adequate blood pressure
- Minimize nephrotoxic medications
- Use alternative, less nephrotoxic agents when possible
- Discontinue the offending agent as soon as possible
- Provide general supportive measures including fluids and RRT, if necessary

| Loop diuretics | Minimize use to prevent AKI  
Little to no benefit in preventing or treating AKI |
| Crystallloids | Equal in efficacy to colloids at preventing AKI in volume-depleted patients.  
Recommended over colloids (KDIGO)  
Use chloride-restricted fluids |

RRT = renal replacement therapy.

Another important factor related to fluid resuscitation is choosing between chloride-liberal and chloride-restricted fluids. Excess chloride is believed to have a negative impact on renal perfusion. Therefore, administering large volumes of chloride-rich fluids may increase the risk of AKI. Most patients who receive crystalloids for shock receive normal saline (0.9% sodium chloride), which contains 154 mEq of chloride per liter. Chloride-restricted fluids include Ringer lactate and PlasmaLyte (109 and 98 mEq of chloride per liter, respectively). In a large trial of almost 3,000 patients, the use of a chloride-restricted fluid resuscitation strategy resulted in fewer patients with moderate to severe AKI and a lower requirement for RRT.\(^{47}\) The fluids used were either crystalloids or colloids, but the chloride-restricted fluids all had chloride concentrations less than 110 mEq/L. An even larger retrospective study of more than 7,000 patients matched patients receiving normal saline for resuscitation with patients receiving a chloride-restricted crystalloid approach (combination of Ringer lactate and normal saline).\(^{48}\) Although in-hospital mortality was significantly lower in the balanced fluid group, there were no differences in the
percentage of patients experiencing AKI with or without the need for dialysis. A meta-analysis of perioperative and critical care fluid resuscitation with chloride-liberal versus chloride-restricted fluids found no difference in mortality between the different crystalloids.\textsuperscript{49} However, chloride-restricted resuscitation decreased the incidence of acute renal failure and hyperchloremic metabolic acidosis. In this analysis, the significant effect was mostly driven by the results of the Yunos et al. trial, which was the only trial in the analysis that included colloids.\textsuperscript{47}

The KDIGO AKI guidelines recommend crystalloids for expanding intravascular volume over albumin or starches.\textsuperscript{50} They do not address the issue of hyperchloremic crystalloids, but most of the literature in this area was published after publication of the KDIGO guidelines. The Kidney Disease Outcomes Quality Initiative (KDOQI) commentary related to the KDIGO AKI guidelines does address the issue of harm related to hyperchloremic fluids but suggests that better prospective data are still warranted before advocating the preferential use of these fluids.\textsuperscript{18} Both KDIGO and KDOQI recommend that vasopressors be used with fluids to prevent AKI in patients with hypovolemic shock, with KDOQI commentators recommending cautious use of dopamine as a first-line vasopressor. Finally, the KDIGO guidelines recommend using a protocol to manage hemodynamic instability (e.g., early goal-directed therapy). However, because the original early goal-directed therapy trial in sepsis did not specifically assess the incidence of AKI and because more recent trials have not shown a benefit to early goal-directed therapy at preventing AKI, the KDOQI commentators do not endorse management by a protocol. It should be noted that the lack of benefit with early goal-directed therapy in more recent trials may be related to an overall improvement in the standard of care (the comparative arm in these trials) for the fluid management of sepsis. Given all of this, to prevent AKI in hypovolemic patients, it seems prudent to use chloride-restricted crystalloids with vasopressors when necessary, as part of a fluid management protocol.

\textbf{Drug-Induced AKI}
Specific recommendations for preventing or treating drug-induced AKI are limited (see Table 26.5). For most drugs, understanding the risk and using alternative, less nephrotoxic agents in patients at high risk of renal failure is the best preventive strategy. Treatment involves supportive care and discontinuing the offending agent as soon as possible. Fortunately, most drug-related causes of AKI are reversible if caught early, with subsequent discontinuation of the nephrotoxin. Medications most associated with renal failure include NSAIDs and selective cyclooxygenase 2 inhibitors; ACEIs and ARBs; vasopressors; β-lactam, sulfonamide, aminoglycoside, and glycopeptide antibiotics; amphotericin B; acyclovir and cisplatin; carboplatin and oxaliplatin; cyclosporine and tacrolimus; and radio-contrast agents. Drug classes with specific recommendations are listed in the paragraphs that follow with the data supporting prevention or treatment strategies.

**ACEIs and ARBs**

Although there are no specific prevention or treatment recommendations for ACEI- or ARB-induced AKI, two important points should be stressed. First, ACEI- or ARB-induced AKI is more likely to occur in patients receiving NSAIDs or diuretics, or in patients who are volume depleted. These risk factors reduce renal perfusion pressure and exacerbate the ACEI or ARB effect on the kidneys. In patients with these risk factors, ACEIs and ARBs should be initiated at low doses and titrated slowly. Even when someone is stabilized on an ACEI/ARB, volume depletion or adding an NSAID or diuretic can increase the likelihood of decreasing GFR.

---

| Aminoglycosides            | • Start at low doses and titrate slowly  
• Avoid prolonged courses, elevated trough concentrations, hypovolemia, concurrent nephrotoxic agents, and overdiuresis  
• Use high-dose extended-interval dosing, if possible  
• Vancomycin  
• Close monitoring when targeting higher trough concentrations  
• Close monitoring when used concomitantly with either aminoglycosides or piperacillin/tazobactam |
| Amphotericin B             | • Use a lipid formulation  
• Liberalize sodium intake, including normal saline boluses before and after administration |
| Sulfonamides, acyclovir, methotrexate (crystalluria) | • Adequate fluid (e.g., normal saline) to achieve a urine output of 100–150 mL/hr  
• For sulfonamide or methotrexate crystalluria, alkalinize the urine |
| Cisplatin                  | • Adequate fluid (e.g., normal saline) to achieve a urine output of 100–150 mL/hr  
• Begin fluid administration 12 hr before infusion and continue for 24 hr  
• In ovarian cancer, may consider administering amifostine before each dose  
• Reduce the dose or use carboplatin instead |
| Calcineurin inhibitors (cyclosporine, tacrolimus) | • Monitor therapeutic drug concentrations closely  
• Avoid drug interactions that increase serum concentrations |
| Radiocontrast agents       | • Use lower doses and minimize diagnostic tests requiring radiocontrast agents  
• Normal saline or sodium bicarbonate infusions up to 12 hr before and 12 hr after administration  
• Moderate- or high-dose statins (for cardiac procedures using contrast)  
• Ascorbic acid (for cardiac procedures using contrast) |

**NSAID** = nonsteroidal anti-inflammatory drug.
Second, an increase in serum creatinine after administering ACEIs/ARBs is not a reason to discontinue therapy. An increase in creatinine of up to 30% is common in the first few weeks after initiating an ACEI/ARB. This increase will remain but will stabilize in the first month of therapy. Only if a patient’s creatinine increases greater than 30% over baseline when initiating an ACEI/ARB should the dose be reduced or the drug discontinued altogether.

Aminoglycosides

Nephrotoxicity is a well-known complication of aminoglycoside therapy. Fortunately, this adverse event is reversible after discontinuation because renal cells can regenerate. Controversy exists regarding the risk factors associated with aminoglycoside nephrotoxicity. Various controlled studies relate certain factors to subsequent toxicity, including a prolonged course or recent course, persistently elevated trough concentrations, hypovolemia, advanced age, liver disease, concurrent nephrotoxic agents, and overdiuresis.

No specific interventions consistently prevent aminoglycoside nephrotoxicity. General measures (e.g., hydrating the patient and avoiding concomitant nephrotoxins) are important. Maintaining appropriate serum concentrations is also recommended; however, no data correlate nephrotoxicity with specific serum concentrations or with therapeutic drug monitoring. In an effort to decrease toxicity and improve efficacy, high-dose extended-interval (“once daily”) aminoglycoside dosing is recommended. Many studies have evaluated the nephrotoxicity of once-daily dosing compared with traditional dosing, and many meta-analyses have subsequently tried to aggregate the results. In two of eight of these meta-analyses, once-daily dosing was associated with less nephrotoxicity, a 26%–40% relative risk reduction. In the others, there was no difference between the two dosing strategies. Although controversial, it seems prudent to use once-daily dosing whenever possible and to institute other general preventive strategies, including therapeutic drug monitoring, when using
Vancomycin

The understanding of vancomycin nephrotoxicity has changed over the years. Early in its use, vancomycin contained many impurities that were believed to lead to nephrotoxicity. Once the clinical formulation was purified, the incidence of nephrotoxicity was 5%–17% in various clinical trials.63–68 This rate increased to as high as 35% of patients when vancomycin was combined with aminoglycosides. In guidelines published in 2009, higher vancomycin trough values (10–20 mcg/mL) were recommended to decrease resistance, enhance tissue penetration, and improve clinical outcomes, especially in serious MRSA (methicillin-resistant Staphylococcus aureus) infections.69 After these recommendations, several studies and a meta-analysis of a variety of hospitalized patients with gram-positive infections showed an increased nephrotoxicity of vancomycin to as high as 34% of patients.70-73 A few other factors were related to this high level, including ICU residence and longer lengths of therapy, but higher trough concentrations had the biggest impact.

As with aminoglycosides, no specific interventions definitively prevent or treat vancomycin nephrotoxicity. Because recent studies suggest that higher vancomycin trough concentrations increase the risk of nephrotoxicity, closer monitoring is advised when targeting trough concentrations above 15 mcg/mL. Certain infections may require these higher concentrations because of the location or the MIC (minimum inhibitory concentration) of the causative organism. In these situations, using an alternative antibiotic may be the most appropriate method to prevent AKI. The incidence of nephrotoxicity is also significantly higher when vancomycin is combined with aminoglycosides63,67 or piperacillin/tazobactam.68,74,75 Because these are antibiotic combinations commonly used in the ICU patient, diligence is warranted in monitoring serum concentrations, maintaining adequate volume status, and avoiding any other nephrotoxins.
Amphotericin B nephrotoxicity occurs commonly, with the GFR falling within the first few weeks of initiating therapy.\textsuperscript{76} Most patients stabilize at 20\%–60\% of normal renal function, but acute renal failure can occur.\textsuperscript{77} The exact mechanism of nephrotoxicity is uncertain but is probably related to decreases in renal blood flow and amphotericin binding to cholesterol in the tubular epithelium, causing tubular necrosis. The decrease in function is also believed to be the result of a feedback mechanism in the kidney where the ion load created by amphotericin in the urine causes vasoconstriction of the afferent arteriole.\textsuperscript{77} Newer lipid formulations of amphotericin significantly decrease the incidence of renal toxicity, with rates decreasing from 40\%–50\% to 8\%–20\%.\textsuperscript{78–81} This lower incidence is believed to be because of a slower release of amphotericin B in the bloodstream and less of the drug available to interact directly with the renal tubules.

Because there is no specific treatment for amphotericin renal toxicity, prevention is key. Treatment usually consists of interrupting amphotericin therapy, which is problematic in patients with certain resistant fungal infections. Newer antifungals, such as the azoles and echinocandins, are not considered nephrotoxic and are appropriate alternatives for certain fungal infections (e.g., candidiasis and aspergillosis) in patients at risk of nephrotoxicity.\textsuperscript{82} Lipid formulations of amphotericin should be used whenever possible to decrease the risk of nephrotoxicity. One of the best nephrotoxicity prevention strategies for either amphotericin deoxycholate or one of the lipid formulations is salt loading.\textsuperscript{77,83} Because of the proposed renal feedback mechanism for nephrotoxicity, maintaining an adequate osmolality in the blood decreases the renal response to the high ionic load in the renal tubules. Liberalizing salt intake and using normal saline for maintenance fluid and intravenous medications is beneficial. In addition to increasing sodium intake, 500 mL of normal saline should be administered over the 30 minutes immediately before and immediately after the amphotericin infusion.\textsuperscript{77} Ideally, the goal is to induce a urinary sodium excretion of 250–300 mmol per day. If not instituted preventively, sodium loading may be beneficial as a treatment to allow for continued
amphotericin B administration. The only other method with data supporting its effectiveness in preventing nephrotoxicity is continuous infusion amphotericin. Acetylcysteine and mannitol are not beneficial in preventing amphotericin toxicity.

**Sulfonamides, Acyclovir, and Methotrexate**

Certain medications cause AKI by crystallizing in the urine and causing tubular obstruction. Examples of these drugs include sulfonamides, acyclovir, and methotrexate. This crystallization can be prevented by administering adequate fluids. Patients should receive fluid to maintain a urine output of 100–150 mL/hour while on these agents. For crystallization secondary to sulfonamides and methotrexate, giving sodium bicarbonate to alkalinize the urine increases crystal solubility.

**Cisplatin**

Because of its efficacy as a cancer chemotherapeutic agent, cisplatin is still commonly used, even though it causes significant direct cellular toxicity in the proximal tubule. Many agents have been evaluated for their potential protection against this nephrotoxicity. At this time, the best method appears to be administering fluid, starting at least 12 hours before cisplatin. This fluid volume should achieve a urine output of at least 100–125 mL/hour. In addition, cisplatin should be infused in normal saline. Fluid administration should then continue for 24 hours after cisplatin administration. Data on administering diuretics such as furosemide or mannitol do not consistently support their effectiveness over saline alone. In ovarian cancer, administering amifostine before each cisplatin dose may be considered to prevent renal oxidative stress and subsequent cisplatin-related nephrotoxicity. Amifostine cost and adverse events, especially hypotension, may limit its use. Finally, cisplatin dose reduction or use of the less nephrotoxic platinum drug carboplatin decreases the risk of nephrotoxicity.

**Calcineurin Inhibitors**
The calcineurin inhibitors, cyclosporine and tacrolimus, are both acutely and chronically nephrotoxic. This can add to the complexity of their therapeutic use, especially when used to prevent renal transplant rejection. Acutely, these agents cause vasoconstriction of afferent arterioles, leading to nephrotoxicity that is reversed with dosage alterations. Chronically, they cause an irreversible tubular toxicity and progressive, ischemic glomerulosclerosis. Patients receiving these agents should take the standard precautions for preventing toxicity (i.e., avoid other nephrotoxic agents, maintain appropriate fluid volume, etc.). Both medications should have drug concentrations monitored closely and doses adjusted accordingly. Concomitant medications should be used carefully to avoid drug interactions that may increase concentrations and associated nephrotoxicity.

Radiocontrast Agents

Whether radiocontrast agents are nephrotoxic is controversial. Studies with control groups are rare (all nonrandomized) and have found no difference in AKI between those that do and do not receive these agents. The proposed mechanism of nephrotoxicity associated with radiocontrast agents is unknown but is believed to be the result of a combination of decreased renal blood flow and direct tubular toxicity. Many studies have evaluated strategies for preventing nephrotoxicity, primarily focusing on normal saline, sodium bicarbonate, acetylcysteine, and statins. Several meta-analyses and guidelines have been developed using these studies. As with amphotericin, an effective preventive strategy appears to be sodium loading. Recommendations include using normal saline at a rate of 100 mL/hour 6–12 hours before and 4–12 hours after administering radiocontrast agents. Obviously, in emergency cases, the pre-administration salt loading may not be possible. Studies have also shown that sodium bicarbonate infusions are more effective than normal saline at preventing radiocontrast-induced AKI, and most subsequent meta-analyses have confirmed this superior benefit. Acetylcysteine has been studied to prevent radiocontrast-induced AKI in several clinical trials with subsequent meta-analyses. These meta-analyses have generally not supported this
intervention because of inconsistent results, but using higher doses may be beneficial. Many studies have evaluated the use of statins in either moderate or high doses to prevent contrast-induced nephropathy after coronary angiography and percutaneous coronary intervention. Several meta-analyses of these trials have shown a consistent benefit of statins in preventing AKI. Ascorbic acid is also effective at preventing AKI after contrast use for coronary angiography. Theophylline has shown benefit in preventing contrast-induced nephrotoxicity, but primarily in patients with normal serum creatinine. Other agents that have been tried without success in this setting are mannitol, furosemide, and fenoldopam. Nonpharmacologic measures such as using lower doses of contrast, minimizing diagnostic tests with contrast, or spacing out these tests can also be used to prevent toxicity.

Ineffective Agents for Renal Protection

For years, low- or renal-dose dopamine was used to maintain renal perfusion and prevent AKI. At doses of 0.5–5 mcg/kg/minute, dopamine has preferential effects on the kidney, causing increased renal perfusion. Many meta-analyses and a large clinical trial have looked at several different outcomes when using low-dose dopamine, including mortality, increases in serum creatinine, development of acute renal failure, need for RRT, and hospital and ICU lengths of stay. Urine output increases in the first 24 hours after adding low-dose dopamine, but that effect diminishes within 48 hours. Low-dose dopamine is therefore no longer recommended for renal protection.

Fenoldopam, a \(D_1\)-specific dopamine agonist, has also been suggested as an agent to prevent or treat AKI in critical care patients. A meta-analysis of studies in cardiac surgery patients found that the incidence of AKI was significantly decreased by fenoldopam. Patients receiving fenoldopam had a higher incidence of hypotension and vasopressor use, and there was no difference in the use of RRT, length of hospital or ICU stay, or mortality. A subsequent, large, randomized, placebo-controlled clinical trial using fenoldopam in cardiac
surgery patients found no differences in use of RRT or mortality. Hypotension was greater in the fenoldopam group. Although another meta-analysis that included both postoperative and critically ill patients found that fenoldopam decreased the incidence of AKI, use of RRT, ICU length of stay, and in-hospital mortality, no large clinical trials have confirmed these results.

The renal-protective effects of nesiritide have been evaluated in patients with acute decompensated heart failure or in those undergoing high-risk cardiac surgeries. In patients with diminished renal function and decompensated heart failure, several studies show no significant effect of nesiritide on measures of renal function (urine output, GFR, changes in creatinine or cystatin C, etc.). Studies using nesiritide to prevent renal dysfunction in patients undergoing high-risk cardiac surgery have yielded mixed results. One prospective trial found no difference in short- or long-term survival or need for dialysis, although there was a lower incidence of AKI in the nesiritide group. Another prospective trial of patients undergoing coronary artery bypass grafting found that perioperative nesiritide resulted in lower rises in creatinine, greater urine output, shorter hospital stays, and lower mortality in the nesiritide group.

The Perioperative Ischemic Evaluation 2 (POISE-2) trial studied aspirin and clonidine perioperatively for patients undergoing noncardiac surgery. Although the primary outcomes of POISE-2 were death or nonfatal MI, a substudy evaluated the impact of the two drugs on AKI. Neither drug decreased the risk of AKI perioperatively; however, there was an increased risk of major bleeding and hypotension as the result of aspirin and clonidine, respectively. Patients who had either a major bleed or hypotension had a higher risk of subsequent AKI.

**CONCLUSION**

In summary, AKI often occurs in ICU settings. It is rarely attributed to a single factor, and most critically ill patients who develop AKI do so as a result of several renal insults occurring simultaneously or in sequence (hemodynamic, septic, and nephrotoxic). The clinical picture is further
complicated in patients with underlying kidney disease and in those receiving nephrotoxic medications. Because many forms of AKI are preventable, patients at risk should be identified early and steps taken to avoid potential renal insults. Treatment of established AKI involves fluids, drug dose adjustment or discontinuation, and supportive care.

LEARNING OBJECTIVES

1. Understand how solute transfer occurs between different modes of intermittent and continuous renal replacement.

2. Compare the advantages and disadvantages of intermittent hemodialysis and continuous renal replacement therapy.

3. List anticoagulation options used for extracorporeal dialytic therapies.

4. Understand how renal replacement therapy fluids affect the transfer of electrolytes during therapy.

5. List filter characteristics that affect solute movement during renal replacement therapies.

7. Understand the drug characteristics that promote clearance by continuous renal replacement therapies.

8. Appreciate the impact of diffusion versus convection on drug clearance.

10. Understand the drug characteristics that promote clearance by plasmapheresis.

11. Appreciate how different components and conditions of the plasmapheresis procedure can affect drug clearance.

12. Know when to dose drugs in patients receiving plasmapheresis.

13. Describe the components of the extracorporeal membrane oxygenation (ECMO) circuit.

14. Identify the factors responsible for alterations in drug pharmacokinetics in patients on ECMO.

15. Recognize the drugs known or predicted to be sequestered by the ECMO circuit.

**ABBREVIATIONS IN THIS CHAPTER**

- **AUC**: Area under the plasma concentration time curve
- **Cl**: Total body clearance
- **Cp**: Concentration in the plasma
- **Cp_{ss}**: Concentration in the plasma at steady state
- **CVVH**: Continuous venovenous hemofiltration
- **CVVHD**: Continuous venovenous hemodialysis
- **CVVHDF**: Continuous venovenous hemodiafiltration
- **E**: Extraction of a drug across an organ or device
- **ECMO**: Extracorporeal membrane oxygenation
INTRODUCTION

Renal replacement therapy comprises a group of techniques that provide dialytic and fluid removal support either alone or in combination. It is estimated that 6% of patients admitted to the intensive care unit (ICU) will receive renal replacement therapy during their hospitalization. In addition to patients with a history of dialysis-dependent chronic kidney disease, patients in the ICU are at increased risk of requiring renal replacement therapy because of acute kidney injury induced by drugs, sepsis, exacerbation of autoimmune diseases, and so forth. The primary goals of renal replacement therapy in ICU patients are to reduce kidney injury and complications related to decreased kidney function.

Prescribed renal replacement therapies can be intermittent or continuous in duration. Intermittent therapies include conventional intermittent hemodialysis (IHD), sustained low-efficiency hemodialysis (SLED) or extended daily hemodialysis (EDD), and intermittent peritoneal dialysis. Continuous renal replacement therapies include two forms of peritoneal dialysis (CAPD [continuous ambulatory peritoneal dialysis] and CCPD [continuous cycler-assisted peritoneal dialysis]) and several forms of dialysis and ultrafiltration (slow continuous ultrafiltration [SCUF], continuous venovenous hemofiltration [CVVH],...
continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF)). A discussion of each technique will follow later in this chapter. An excellent review that discusses the various continuous renal replacement therapies has been published. In general, renal replacement therapy techniques are capable of removing water and metabolic waste products (often called solute) by transport across a semipermeable membrane. What differentiates each technique is the method in which water and solute are removed. Ultrafiltration is the process of water removal without the appreciable loss of solutes. Hypervolemic conditions (e.g., heart failure) are indications for isolated ultrafiltration or SCUF. When ultrafiltration flow rates are increased (usually greater than 1,000 mL per hour), solute is removed as water carries it across a semipermeable membrane in response to a transmembrane pressure gradient. The process of removing solute with water from blood is termed hemofiltration. When it is performed in a continuous mode (e.g., CVVH), replacement fluid is adjusted at either the prefilter or the postfilter location. Ultrafiltration through CVVH can remove larger molecular weight solutes than diffusion alone (e.g., CVVHD). Because CVVHD uses diffusion to remove solutes, a dialysate is needed to create a concentration gradient. To effectively remove both solute and fluid, several extracorporeal techniques, including IHD, SLED/EDD, and CVVHDF, can be used. Choosing a modality is controversial and is usually determined by the ICU physician and/or nephrologist depending on the clinical needs of the patient. However, continuous forms of renal replacement therapy are preferred over IHD in patients who are hemodynamically unstable or who have increased intracranial pressure or brain edema (e.g., acute brain injury).

Outcomes with Renal Replacement Therapy

Patients developing acute kidney injury tend to have prolonged ICU and hospital stays and have in-hospital mortality rates of 50%–70%. For survivors, health-related quality of life is reduced compared with the
For ICU survivors with and without acute kidney injury, the health-related quality of life is similar at 6 months; however, it is still lower than in the general population. There is considerable interest in determining the effect of different renal replacement therapies on long-term kidney function recovery. Studies evaluating short-term kidney function recovery have not found a difference between continuous renal replacement therapy and IHD. For long-term recovery comparisons, observational and cohort studies have suggested that patients receiving continuous renal replacement therapy compared with intermittent therapies are less likely to progress to chronic kidney disease requiring maintenance hemodialysis. Although a cause and effect has not been determined, it is believed that less hemodynamic instability occurs during continuous renal replacement therapy. Many patients regaining kidney function after acute kidney injury will have advanced kidney disease compared with their baseline kidney function.

**RENAL REPLACEMENT THERAPY**

Of the available forms of renal replacement therapy, IHD and continuous therapies are used most commonly in adult critically ill patients in developed countries. Peritoneal dialysis is infrequently used because of its inability to effectively and rapidly remove metabolic waste products in hypercatabolic critically ill patients. In addition, it has a relative contraindication in patients with recent intra-abdominal surgery and pathologies. Pediatric and neonatal patients with acute kidney injury often receive peritoneal dialysis, but controversy remains regarding the most appropriate therapy. In developing countries, peritoneal dialysis provides a means for renal replacement therapy when other, more technical procedures may not be feasible.

**COMPONENTS OF THERAPIES**

**Filters and Dialyzers**
Technologies to improve the biocompatibility and permeability of filters used in IHD and continuous renal replacement therapies have evolved over several decades, from cellulosic membranes primary used in early IHD to synthetic polymers (e.g., polysulfone, polyamide, polymethylmethacrylate, polyacrylonitrile) used most often today. Other important features of newer filter membranes include a larger, more uniform pore size, increased hydrophobicity, and greater biocompatibility. Binding to these filters has been described for select drugs (e.g., aminoglycosides)\textsuperscript{22} and cytokines.\textsuperscript{23} Attempts at removing cytokines during continuous renal replacement therapies have been investigated using both hemodialysis and hemofiltration. Cytokine removal during CVVH would likely require a highly permeable membrane with production of a large amount of filtrate. Cytokines may also adsorb to these membranes. However, because the surface area of these filters quickly becomes saturated, frequent filter changes may be required. Cole et al. investigated the adsorption of several interleukins and tissue necrosis factor to a polyacrylonitrile membrane (AN69) using donated blood from six healthy volunteers in an ex vivo model of CVVHD and CVVH. Cytokine adsorption was only minor.\textsuperscript{24} Several studies have failed to show a correlation between cytokine removal and improved outcomes.\textsuperscript{25,26}

The permeability of a filter directly correlates with the ability of water to cross and is described as the ultrafiltration coefficient (Kuf). The Kuf is determined by the volume of fluid that crosses the membrane in milliliters per hour per millimeter of mercury. If the membrane Kuf is low, its permeability to water is also low, and a higher transmembrane pressure is required to generate an ultra-filtrate. Membranes with a higher Kuf produce a greater amount of ultrafiltrate at equivalent or lower transmembrane pressures. Small solutes (e.g., urea) are primarily removed by diffusion. In addition to size, the ability of solutes to cross a membrane is a function of the thickness and porosity and is expressed as the diffusion coefficient.

To remove larger solutes, convection is needed. The rate of convection is related to how fast water crosses the membrane, size of the solute, and pore size of the membrane. The ability of solutes to
cross a membrane during convection is determined by the solute's sieving coefficient. A solute with a sieving coefficient of 1.0 crosses the membrane, whereas a solute with a value of zero is impermeable. For IHD, filters with a greater urea clearance are required because of the short therapy duration. For continuous renal replacement therapies, however, lower urea clearance is acceptable because of the continuous duration. For convection (CVVH), the Kuf must be greater than 6–8 mL/hour/mm Hg to produce an ultrafiltration rate of 15–20 mL/minute. For diffusive clearance (IHD, CVVHD, or CVVHDF), solutes must pass through the membrane quickly to prevent equilibration between the plasma and the dialysate.

**Anticoagulation**

Activation of the intrinsic and extrinsic coagulation pathway occurs, in addition to platelet activation, when blood contacts the surface of an extracorporeal circuit. Because of this blood-circuit interface, anticoagulation is needed for most patients. In patients who are critically ill, this may be problematic because many have an increased tendency for bleeding given concomitant hepatic impairment. The need for anticoagulation must be balanced with the increased risk of bleeding. One advantage of peritoneal dialysis over IHD and continuous renal replacement therapy is that no anticoagulation is required.

Anticoagulation during IHD usually consists of a heparin bolus given at the beginning of treatment with an additional bolus dose or infusion given during treatment. For patients at high risk of bleeding, a “no-heparin” or minimum-dose heparin option is usually chosen. Other anticoagulation options include trisodium citrate dialysate or regional anticoagulation with trisodium citrate or prostacyclin. In heparin-induced thrombocytopenia, a no-heparin approach is preferred with a direct thrombin inhibitor as the anticoagulant of choice. The choice of an anticoagulant and its dose should be patient-specific to reduce the likelihood of bleeding events.

Several agents have been used to anticoagulate the extracorporeal circuit in continuous renal replacement therapy including unfractionated heparin, low-molecular-weight heparin, trisodium citrate, direct
thrombin inhibitors, and prostacyclin. Regional trisodium citrate is generally preferred in the absence of a contraindication (e.g., severe liver failure). Although trisodium citrate has the advantage of reduced bleeding, metabolic acidosis and hypocalcemia can occur in patients with reduced liver function. Other complications include alkalosis, hypernatremia, and hypercalcemia. The largest disadvantage of trisodium citrate is its complexity of administration and monitoring. However, with the use of a specific protocol, it can safely be used. Unfractionated heparin has several advantages over trisodium citrate including its wide availability, familiarity, and easy of monitoring. The disadvantages of unfractionated heparin include increased risk of bleeding, unpredictable kinetics, risk of heparin-induced thrombocytopenia, and heparin resistance. Regardless of the anticoagulant selected for use, each institution should have a protocol in place to reduce the possibility of unwanted adverse effects.

Composition of Dialysate and Replacement Fluids

In general, dialysate fluids for IHD, peritoneal dialysis, and continuous renal replacement therapies mimic physiological consistency. However, they can be modified to enhance the elimination of electrolytes. For example, if hypercalcemia is present, the dialysate will contain a lower amount of calcium. Replacement fluids can also be tailored to ensure that blood solutes have a composition that is physiologic. Although there are several choices for commercial premade solutions, Table 27.1 gives examples of the different types of dialysate and replacement fluids used in IHD, peritoneal dialysis, CVVH, and CVVHD.

Intermittent Techniques

Intermittent Hemodialysis

Solute removal during IHD and CVVHD occurs primarily by diffusion.
The principal differences between CVVHD and IHD are the duration and frequency of treatment and the flow rates for blood and dialysate. Table 27.2 lists flow rate characteristics (blood, dialysate, and ultrafiltration), mechanisms for solute removal, and therapy durations for both continuous and intermittent renal replacement therapies. Several advantages and disadvantages are associated with each of these therapies (Table 27.3). An advantage of IHD is the rapid removal of solutes and water. This is most important in the setting of hyperkalemia, certain intoxications, and severe fluid overload. However, hypotension is a common cause for interrupting or stopping IHD and occurs during 20%–30% of treatments. Patients with acute kidney injury are often intolerant of IHD, and it is estimated that up to 10% of these patients cannot tolerate this form of therapy.27

**Sustained Low Efficiency Dialysis and Extended Daily Dialysis**

Sustained low-efficiency dialysis and EDD are performed using conventional hemodialysis machines, but with modified blood and dialysate flow rates. A typical blood flow rate is 200 mL/minute during SLED/EDD versus up to about 450 mL/minute with conventional IHD. Dialysate flow rate is about 300 mL/minute during SLED/EDD versus up to 800 mL/minute with conventional IHD sessions. The therapy duration is longer during SLED/EDD (6–12 hours) than during conventional IHD (4 hours), but it is shorter than during continuous renal replacement therapy. Longer treatment duration allows for better hemodynamic stability than with IHD. In addition, because of its intermittent nature, SLED/EDD enables time away from therapy to perform various tests and procedures without affecting solute clearance and fluid management treatment goals.

\textsuperscript{a}Dialysate flow rates are in milliliters per minute for intermittent and milliliters per hour for continuous therapies.

\textsuperscript{b}Because of the slow rate at which fluid is removed during CVVHD, ultrafiltration has no impact on solute removal.

CVVH = continuous venovenous hemofiltration; EDD = extended daily dialysis; SLED = sustained low-efficiency dialysis; IHD = intermittent hemodialysis; CWHD = continuous venovenous hemodialysis; CVVHDF = continuous venovenous hemodiafiltration

**Peritoneal Dialysis (intermittent or continuous)**

Peritoneal dialysis differs from intermittent or continuous renal
replacement therapies because it uses the lining of the abdominal cavity to act as a dialysis membrane. However, dialysate is also needed for peritoneal dialysis in order to create a concentration gradient to enable solute and water removal. Several commercial dialysate solutions are available for peritoneal dialysis, and all contain a mixture of electrolytes, lactate, and glucose.

**Continuous Renal Replacement Techniques**

**Slow Continuous Ultrafiltration**

Ultrafiltration uses pressure to force plasma water across a semipermeable membrane. The driving force for flow is dependent on the difference between the positive pressure that is created on the blood side of the membrane and the negative pressure that is created on the opposite side of the membrane. Although the hydrostatic pressure has a large impact on removal of fluid, there is a minimal effect on solute removal. When isolated ultrafiltration is provided in a continuous mode, it is typically termed SCUF. Figure 27.1 represents a typical SCUF circuit.

**Continuous Venovenous Hemodialysis**

Diffusion occurs when a solute moves across a semipermeable membrane in response to a concentration gradient. The ability to transverse the membrane depends on membrane porosity and the molecular weight of the solute. The ability to diffuse is inversely proportional to the solute molecular weight. For diffusion, the greatest impact on solute clearance is for low-molecular-weight molecules (less than 500 g/mol). Other factors that influence solute clearance are membrane characteristics (e.g., surface area and thickness) and solution temperature. For diffusion to occur, a concentration gradient must be maintained. Blood (containing a high-solute concentration) flows across the hollow fiber membranes, whereas dialysate (containing an absent or low-solute concentration) flows countercurrent on the other side of the dialyzer membrane. If the dialysate contains a
higher concentration of solute than blood, diffusion will occur in the opposite direction (e.g., from dialysate to blood). In general, this “backward flow” is undesirable. One exception may be the backward flow of bicarbonate in metabolic acidosis. In 2004, an ISMP Canada Safety Bulletin reported the deaths of two patients who inadvertently received dialysate containing about 57 mEq per liter of potassium chloride. Because dialysate fluid is not under a condition of recirculation, equilibrium is not obtained. Figure 27.2 shows the diffusion process as it occurs in IHD (and CVVHD). However, although conventional IHD usually occurs over 4 hours, CVVHD is a form of continuous renal replacement therapy. Figure 27.3 is a graphical depiction of CVVHD.

</table>
• Can be used in most hemodynamically unstable critically ill patients
• Several options to choose from (i.e., CVVH, CVVHD, CVVHDF)
• Allows for full nutritional support
• May be safer for patients with brain injuries
• May have a beneficial effect in patients in septic shock
• May increase the likelihood of renal recovery

Disadvantages
• Requires the purchase of specific devices
• Higher cost for supplies
• Requires a dedicated ICU nurse
• Usually requires continuous anticoagulation
• Can cause hypothermia
• Can cause life-threatening depletion of several electrolytes if not monitored closely and replaced

**Figure 27.1** Slow continuous ultrafiltration (SCUF) circuit.

For slow continuous ultrafiltration (SCUF), blood is filtered through a semipermeable membrane under pressure, producing an ultrafiltrate. Because fluid removal is minimal, a replacement solution is not needed. The primary indication for SCUF is volume overload.

**Continuous Venovenous Hemofiltration**

The ability to remove medium- and high-molecular-weight solutes (up to
15,000 g/mol) using extracorporeal techniques requires convection. Convection occurs when solutes are transported across a semipermeable membrane with the flow of water under the influence of a pressure gradient. The hemofilter membranes have enhanced permeability to enable removal of higher molecular weight solutes.\textsuperscript{30,31} Figure 27.4 shows the blood, water, and ultra-filtration components of convection. The clearance of solute shown during convection occurs though solvent drag.

Hemofiltration differs from ultrafiltration in that the flow across the filter is increased. To provide adequate hemofiltration, at least 1 L of water per hour should cross the membrane.\textsuperscript{32} Figure 27.5 provides an example of a typical CVVH circuit showing both pre- and postfilter replacement fluid administration.

**Continuous Venovenous Hemodiafiltration**

Continuous venovenous hemodiafiltration uses both diffusion and convection to remove water and solute (Figure 27.6).

**Box 27.1. Characteristics of Drugs That Enhance Dialytic Clearance**

- ↓ Molecular weight/size
- ↑ Hydrophilicity
- ↓ Protein binding
- ↓ Volume of distribution
- ↑ Percentage of clearance by kidneys
- ↑ Percentage of clearance by nonrenal routes significantly altered by critical illness
DRUG-RELATED CHARACTERISTICS AND CLEARANCE BY CONTINUOUS EXTRACORPOREAL DIALYTIC TECHNIQUES

The removal of drugs by continuous as well as intermittent dialytic techniques is dependent on the physicochemical characteristics of the drugs and the characteristics of the dialytic procedure. The primary physicochemical characteristics that predict whether a drug will be removed by a dialytic technique are its molecular weight, degree of hydrophilicity, protein binding, volume of distribution (Vd), and whether the kidneys represent the primary clearance pathway (Box 27.1).

Molecular Weight

A drug with a molecular weight of less than 500 g/mol is readily removed by extracorporeal clearance methods that use diffusion. The clearance of drugs with higher molecular weights is enhanced with techniques that use high-flux membranes.

Hydrophilicity vs. Lipophilicity

Drugs are classified by their lipophilic to hydrophilic status by log P values. The log P is a partition coefficient defined as the log of the ratio of the concentration of nonionized drug between oil (lipophilic) and aqueous (hydrophilic) phases. It is often necessary to adjust the pH of the aqueous phase to optimize for the presence of the nonionized form of the drug when determining partition coefficients. A lower log P value indicates that the drug is more hydrophilic, whereas higher log P values indicate improved lipophilicity. Drugs that are more hydrophobic have a greater ability to diffuse through lipid bilayers of cells. Hydrophilic drugs, because of their charges, require transporters to move across cellular membranes.
Diffusion occurs when solute moves from an area of higher concentration to an area of lower concentration. Renal replacement therapies that use diffusion do not allow for equilibrium. To prevent equilibrium, these therapies use a countercurrent dialysate solution (e.g., a dialysate). Diffusion is responsible for removing small molecular weight molecules.

**Figure 27.2** Intermittent hemodialysis circuit.

**Figure 27.3** Continuous venovenous hemodialysis (CVVHD) circuit.
Continuous venovenous hemodialysis (CVVHD) uses the principle of diffusion and is given continuously, ideally over 24 hours.

The hydrophilic/hydrophobic characteristics can influence the absorption, distribution, and excretion of drugs. Drugs and metabolites that are cleared by the kidney are typically hydrophilic. They are typically cleared by dialytic techniques because of their presence in the intravascular compartment (the eliminating compartment for dialytic techniques). For hydrophilic compounds, charges (positive or negative) can result in interactions with extra-corporeal membranes that can lead to drug adsorption. Determination of adsorption requires the assessment of drug concentrations in the effluent and not just arterial and venous port measurements. Gentamicin (log P -3.1) is an example of a drug that is documented to adsorb to the polyacrylonitrile extracorporeal filter membrane. A recent publication showed adsorption of teicoplanin by polysulfone and polymethylmethacrylate membranes.
**Figure 27.4** Continuous venovenous hemofiltration circuit demonstrating movement of blood flow and solutes.

Convection occurs when solutes are transported across a semipermeable membrane with the flow of water and under the influence of pressure. As flow increases, so does the movement of solutes. This movement is called “solute drag.” Convection can remove middle to large molecular weight molecules.

**Figure 27.5** Continuous venovenous hemofiltration (CVVH) circuit incorporating pre- and post-filter replacement fluids.

Continuous venovenous hemofiltration (CVVH) uses the principle of convection. Because CVVH requires the production of a large ultrafiltrate, replacement fluids are added either prefilter (predilution) or postfilter (postdilution), or both. Convection removes middle to large molecular weight molecules.
Protein Binding

The extent of protein binding is important for determining the Vd and exposure of a drug to its tissue sites compared with the intravascular compartment. The clearance of drugs by dialytic methods, as with filtration clearance by the endogenous kidney, is dependent on the fraction of unbound drug. Drugs that are more highly protein bound (e.g., greater than 80% protein bound) are less likely to be removed by dialytic techniques. Bound drugs are complexed with high-molecular-weight proteins, with albumin (69,000 g/mol) being a common protein for binding acidic drugs. It is customary to consult common drug dosing references and product literature to ascertain the reported unbound fraction of a drug. However, the sieving coefficient can also be determined experimentally under conditions of isolated ultrafiltration or referenced from the literature. The sieving coefficient is the ratio of drug concentration in the ultrafiltrate to the prefilter plasma concentration. Either the sieving coefficient or the unbound fraction is necessary for estimating drug clearance during continuous renal replacement therapy. Sieving coefficients typically, but not always, correspond to the unbound fraction.

The degree of protein binding can be decreased by competitive displacers in the plasma including other concomitant highly protein bound drugs and uremic toxins. Decreased albumin concentrations in kidney and hepatic diseases can also reduce protein binding. Increased protein binding can result from increased α₁-acid glycoprotein concentrations found in acute care and inflamed patients.
Because $\alpha_1$-acid glycoprotein binds basic drugs, increased binding will not be observed for acidic drugs. The systemic pH can also influence the protein binding of drugs in critical care patients.

**Volume of Distribution**

The Vd of a drug is defined as a theoretical volume that the total amount of administered drug would have to occupy, if uniformly distributed, to provide the same concentration as blood plasma. It is most influenced by protein binding and log P. Drugs that have high plasma protein binding have small Vd values. Drugs that have high tissue protein binding and low plasma protein binding typically have large Vd values. Factors described earlier (under Protein Binding) will also influence the Vd of drugs. Because extracorporeal techniques remove solutes from blood or plasma, drugs with smaller Vd values (e.g., less than 1 L/ kg) are more likely to be removed by dialytic techniques. The duration of the dialytic technique will also affect the degree of influence of Vd on drug clearance. The likelihood of clearance for drugs with large Vd values increases as the duration of the dialytic procedure increases. The increased time allows drugs to transfer between tissue and vascular compartments. This is particularly important for drugs with larger Vd values. Moxifloxacin (Vd 1.7–2.7 L/kg) is an example whereby clearance is 95 mL/minute with conventional IHD and 33 mL/minute with extended daily dialysis.\(^{39}\) However, the moxifloxacin half-life is shorter on extended dialysis (6 hours) than on IHD (12 hours).\(^{39}\) Readers are referred to a recent review on antibiotic dosing during extended dialysis.\(^{40}\)

**Clearance Pathways**

The clearance pathway for a drug is also important for determining the impact of dialytic clearance on total body clearance. In acute and chronic kidney diseases, dialytic modalities are important for enhancing the clearance of drugs that undergo a significant percentage of clearance by the renal route. As kidney function declines, the total body
clearance of drugs that are excreted primarily by the renal route declines significantly. The contribution of clearance by extracorporeal techniques, renal pathways, and non-renal pathways to total body clearance is determined by equation 27.1:

\[
\text{clearance}_{\text{total}} = \text{clearance}_{\text{nonrenal}} + \text{clearance}_{\text{residual renal}} + \text{clearance}_{\text{extracorporeal}} \quad \text{(equation 27.1)}
\]

The terms in this equation are total body clearance (\(\text{clearance}_{\text{total}}\)), nonrenal clearance (\(\text{clearance}_{\text{nonrenal}}\)), renal clearance (\(\text{clearance}_{\text{residual renal}}\)), and extracorporeal clearance (\(\text{clearance}_{\text{extracorporeal}}\)). The equation shows that clearance processes are additive.

Several clinical cases require particular attention with respect to clearance. Special consideration is required in drug conditions where nonrenal clearance can also decline as kidney function declines since the drug product literature values for unaltered nonrenal clearance may not be valid under this condition. As an example, cytochrome P450 (CYP) 3A expression and function is significantly reduced in chronic kidney disease.\(^{41}\) Patients receiving drugs that undergo predominant nonrenal clearance through CYP3A will likely have reductions in this clearance pathway necessitating drug dosing adjustments. Another special consideration is the case of drug combinations. In this scenario, one compound may have a predominant renal clearance pathway, whereas the other compound is predominantly cleared through nonrenal routes. Another consideration is the contribution of residual renal function to total body clearance. It is often assumed that patients in the ICU who require dialytic techniques have a drug clearance of 0 mL/minute. However, some patients can have significant kidney function that can result in a drug clearance that is considerably higher than predicted. In these circumstances, it is important to remember to add the estimated residual renal clearance to the clearance by nonrenal and extracorporeal pathways to avoid drug underdosing.
EXTRACORPOREAL TECHNIQUES

Diffusion

Drug clearance during continuous renal replacement therapies using a dialysis component occurs through diffusion. Several equations can be used to estimate this clearance. In the body or by extracorporeal devices, clearance is calculated as \( Q \times E \), where \( Q \) is a flow rate, and \( E \) is the extraction of the drug across the organ or device. The extraction across the dialyzer is governed by the unbound fraction of the drug. Extraction can be measured by the difference between the prefiltter (arterial) concentration and the postfilter (venous) concentration divided by the prefiltter concentration: \( E = \frac{\text{arterial} - \text{venous}}{\text{arterial}} \). The clearance can be estimated either by the unbound fraction or by \( E \) multiplied by the dialysate flow rate (equation 27.2). Dialytic clearance estimates by this approach are amenable for use in the clinical environment.

\[
\text{clearance} = f_{ub} \text{ (or } E) \times Q_{\text{dialysate}} \text{ (equation 27.2)}
\]

The dialytic clearance can also be measured during the continuous renal replacement procedure, but this requires more laborious methods that are usually reserved for research studies. These methods are analogous to the calculations used to measure drug clearance by the renal route. For these assessments, the dialysate effluent is collected at intervals, the volume is measured, and the concentration of drug is determined by an analytic method. After multiplying dialysate volumes by their respective concentrations, drug amount determinations are obtained. The amounts are then summed over the intervals and divided by the area under the plasma concentration time curve (AUC) that corresponds to this total time period; this is shown in equation 27.3. Determination of the AUC requires serial blood sampling over the collection period.

\[
\text{clearance}_{\text{dialysis}} = \frac{\Sigma (\text{concentration}_{\text{dialysate}} \times \text{volume})}{\text{AUC}_{\text{over collection time}}} \text{ (equation 27.3)}
\]
Convection/Ultrafiltration

Drug clearance during continuous renal replacement therapies using an ultrafiltration component occurs through convection. Several clearance equations can be used to estimate convection clearance. Clearance is calculated as $Q \times E$; where $Q$ is the ultrafiltration flow rate, and $E$ is the extraction of the drug across the filter. The extraction across the filter is governed by the available unbound fraction of the drug. Extraction is measured by the ratio of drug in the ultrafiltrate to the prefilter concentration: $E = \frac{[\text{ultrafiltrate}]}{[\text{arterial}]}$. This determination of $E$ is also called the sieving coefficient. A value of 1 indicates free passage of the solute across the membrane under the condition of isolated ultrafiltration. The clearance can be estimated either by the unbound fraction or by $E$ multiplied by the ultrafiltration flow rate (equation 27.4). Equation 27.4 is used when fluids are administered postdilution.

$$\text{clearance} = f_{ub} \times Q_{\text{ultrafiltration}} \quad (\text{equation 27.4})$$

If fluids are administered in the predilution mode, equation 27.5 should be used.

$$\text{clearance} = f_{ub} \times Q_{\text{ultrafiltration}} \times \left[ \frac{Q_{\text{blood}}}{(Q_{\text{blood}} + Q_{\text{replacement}})} \right] \quad (\text{equation 27.5})$$

Clearance estimates by these approaches can be used in the clinical environment.

The ultrafiltration clearance, like the dialysate clearance, can also be measured during continuous renal replacement therapy. For these assessments, the ultrafiltration effluent is collected at intervals, the volume measured, and the concentration of drug determined by an analytic method. After multiplying ultrafiltrate volumes by their respective concentrations, drug amount results are obtained. These amounts are then summed over the intervals and divided by the AUC that corresponds to this total time period; this is shown in equation 27.6. Determination of the AUC requires serial blood sampling over the collection period.
Combined Dialysis with Convection/Ultrafiltration

It is now common in the ICU to use a combination of dialysis and ultrafiltration during continuous renal replacement therapy. Therefore, the clinician needs to know how to account for clearance through this combination. The clearance by the combination of dialysis and ultrafiltration can be estimated by multiplying the unbound fraction by the total effluent rate, which is composed of the combination of dialysate flow rate and ultrafiltration flow rate (equation 27.7). Clearance estimates by this approach are used in the clinical environment.

\[
\text{clearance}_{\text{ultrafiltration}} = \left[ \sum (\text{concentration}_{\text{ultrafiltrate}} \times \text{volume}) \right] / \text{AUC}_{\text{over collection time}} \quad (\text{equation 27.6})
\]

\[
\text{clearance} = f_{\text{ub}} \times (Q_{\text{dialysate}} + Q_{\text{ultrafiltration}}) \quad (\text{equation 27.7})
\]

For measuring clearance through the combination of dialysis and ultrafiltration, the total effluent is collected at intervals, the volume is measured, and the concentration of drug is determined through an analytic method. After multiplying effluent volumes by their respective concentrations, drug amounts result. These amounts are then summed over the intervals and divided by the AUC that corresponds to this total time; this is shown in equation 27.8.

\[
\text{clearance}_{\text{effluent}} = \left[ \sum (\text{concentration}_{\text{effluent}} \times \text{volume}) \right] / \text{AUC}_{\text{over collection time}} \quad (\text{equation 27.8})
\]

As mentioned at the beginning of this section, to adequately determine drug clearance, an assessment of determinants of total clearance is required. Therefore, the nonrenal clearance and residual renal clearance of the drug must be added to the clearance estimated or measured from the continuous renal replacement therapy (equation 27.1). Box 27.2 summarizes the clearance equations discussed in this section. Table 27.4 provides the abstracted clearance data for drugs during various continuous renal replacement therapies.
ACUTE VS. CHRONIC KIDNEY DISEASE AND PHARMACOKINETIC ALTERATIONS

There is a considerable body of literature to show the influence of chronic kidney disease on the pharmacokinetics of drugs.\textsuperscript{42-44} However, there is a paucity of comparable data in patients with acute kidney injury. According to the available data, it is reasonable to assume similar changes in acute and chronic kidney diseases. However, there are differences that require consideration (Table 27.5), which are discussed in the following sections. Patients with acute kidney disease typically receive continuous versus intermittent dialytic techniques. The longer treatment duration will affect drugs with a large Vd secondary to more time for net transfer from tissue to vascular compartments. The incorporation of convection with high-flux membranes in continuous renal replacement therapy will enhance the removal of drugs with high molecular weights. Drug pharmacokinetics can be altered in critical care patients secondary to the physiological changes induced by organ alterations such as acute kidney injury, hepatic disease, cardiac failure, or generalized inflammatory states, occurring alone or in combination. Changes to drug absorption, distribution, metabolism, and excretion processes are reported and are reviewed.

Absorption

Because many medications are administered by the intravenous route to patients in the ICU, changes to oral bioavailability secondary to alterations in absorption may be less problematic. However, medication administered by other extravascular routes, including subcutaneous and intramuscular, can result in alterations in absorption and for subsequent bioavailability. Several processes are responsible changes to the systemic bioavailability of medications in the critical care population and are described.
Box 27.2. Equations for Clearance Determination in Continuous Renal Replacement Therapies

**Diffusion**

Eq. 2: Clearance = \( f_{ub} \) (or \( E \)) \( \times Q_{dialysate} \)

Eq. 3: Clearance\(_{dialysis} = \left\lfloor \frac{\text{concentration}_{dialysate} \times \text{volume}}{\text{AUC}_{\text{over collection time}}} \right\rfloor \)

**Convection**

Eq. 4: Clearance = \( f_{ub} \) (or \( E \)) \( \times Q_{ultrafiltration} \) (if using predilution fluids)

Eq. 5: Clearance = \( f_{ub} \) (or \( E \)) \( \times Q_{ultrafiltration} \times \left[ \frac{Q_{blood}}{Q_{blood} + Q_{Replacement}} \right] \) (if using postdilution fluids)

Eq. 6: Clearance\(_{ultrafiltration} = \left\lfloor \frac{\text{concentration}_{ultrafiltrate} \times \text{volume}}{\text{AUC}_{\text{over collection time}}} \right\rfloor \)

**Diffusion + Convection**

Eq. 7: Clearance = \( f_{ub} \times (Q_{dialysate} + Q_{ultrafiltration}) \)

Eq. 8: Clearance\(_{effluent} = \left\lfloor \frac{\text{concentration}_{effluent} \times \text{volume}}{\text{AUC}_{\text{over collection time}}} \right\rfloor \)

Cl\textsubscript{TB} = total body clearance; CI\textsubscript{RRT} = renal replacement therapy clearance; DFR = dialysate flow rate; MW = molecular weight; NR = not reported; PB = protein binding; REF = reference; SA = surface area; UFR = ultrafiltration flow rate; Vd = volume of distribution.

Slowing of gastric emptying, or gastroparesis, is common in the ICU patient and can decrease the rate of drug absorption, resulting in a prolonged time (T\text{max}) to reach the maximum plasma concentration (C\text{max}). In addition, patients may have concomitant diseases such as diabetes mellitus or be prescribed medications (e.g., opiates, tricyclic antidepressants, phenothiazines, and calcium channel blockers) that can slow gastric emptying.

Metabolic acidosis is common in critical care patients and can change the fraction of drug in the ionized versus nonionized state, resulting in changes to bioavailability. In addition, critical care patients are often prescribed ulcer prophylaxis and/or treatment regimens that contain drugs that can increase gastric pH, resulting in changes to the systemic bioavailability of prescribed medications. Concomitant use of proton pump inhibitors will reduce the absorption of iron, calcium, magnesium, and vitamin B\textsubscript{12}. The pH can also influence the availability of active pharmaceuticals from prodrug formulations. Binding of medications in the gut, such as the interaction between sucral-fate and fluoroquinolones, can reduce oral bioavailability.

Reduction in first-pass metabolism can occur in critically ill patients secondary to decreases in the function of CYP metabolizing enzymes in the gut and liver. This can result in increases in the systemic bioavailability of CYP substrates. Other conditions such as edema of the gut and impaired small bowel function can also change the bioavailability of medications in the critical care population.

**Distribution**

Distribution volume is related to plasma protein binding and tissue binding. Two common plasma proteins are albumin (which binds acidic drugs) and \(\alpha_1\)-acid glycoprotein (which binds basic drugs). Although chronic kidney disease is associated with reduced plasma protein
concentrations, acute care patients can have increased protein binding of basic drugs secondary to increased $\alpha_1$-acid glycoprotein concentrations.\textsuperscript{38} This scenario would predict a potential increase in the removal of acid drugs and a decrease in the removal of basic drugs during continuous renal replacement therapies. Patients with acute illness can also have redistribution of albumin from the intravascular to the extravascular compartments secondary to capillary leak syndrome, resulting in significant changes to the Vd of hydrophilic drugs.\textsuperscript{45} Common antibiotic examples include ceftriaxone, ertapenem, daptomycin, and aztreonam.\textsuperscript{46} It is often recommended to consider using loading doses of hydrophilic drugs in critical care patients. Alterations in drug to albumin binding have recently been extensively reviewed.\textsuperscript{46} Increases in body water that occur with volume overload in acute kidney disease can result in increases in the distribution volume of hydrophilic drugs (e.g., aminoglycoside antibiotics).

**Table 27.5** Differences Between Acute and Chronic Kidney Diseases That May Impact Drug Pharmacokinetics

**Metabolism**
Cytochrome P450 enzymes can be decreased up to 35%, according to studies using experimental models of chronic kidney disease, and decreased up to 63%, according to clinical studies. In addition, in patients with chronic kidney disease, the function of CYP3A4 can be improved immediately after hemodialysis. The function of metabolic pathways in acute kidney injury and other representative diseases in critically ill patients is not well defined. Reductions in the nonrenal clearance of imipenem and vancomycin have been reported in patients with acute kidney injury. The clearance reduction was reported to be less severe than in patients with chronic kidney disease requiring IHD: 90 mL/minute versus 50 mL/minute, respectively, for imipenem and 15 mL/minute versus 5 mL/minute, respectively, for vancomycin. The duration of acute kidney injury can also influence the reduction in nonrenal clearance. Macias et al. reported that as the length of continuous renal replacement therapy increased, the nonrenal clearance was more significantly affected.

**Excretion**

Drugs that undergo excretion primarily through the kidneys (aminoglycosides, penicillins) will have significant reductions in total body clearance through decreases in renal clearance. The Dettli method is used to predict the fraction of clearance of a patient with chronic kidney disease relative to the expected clearance in a healthy individual (e.g., Q factor). It can be used to predict changes in the dose, interval, or combination of dose and interval in patients with chronic kidney disease. However, it has not been tested under acutely changing kidney function conditions.

Endogenous clearance (both renal and nonrenal) can be different in acute versus chronic kidney diseases. It is generally recognized that residual renal clearances will be higher in the setting of acute versus chronic kidney disease. In addition, clearance can be increased in critically ill patients secondary to concomitant drugs prescribed to maintain adequate perfusion pressure. Mechanical ventilation can also contribute to increased clearance. A recent review provides
additional discussion of the potential for augmented renal clearance in critical care patients. Several transport proteins (e.g., P-glycoprotein, organic anion and cation transporters) contribute to drug secretion in the kidney tubules and can be affected by chronic kidney disease. The effects of critical illness on transport processes have not been evaluated. In addition, the influence of metabolic by-products (e.g., uremic toxins) on transporters in acute kidney injury is currently unknown.

**DRUG DOSING STRATEGIES/ PHARMACOKINETICS**

A previous section of this chapter reviewed the basic equations for estimating and measuring clearance during continuous renal replacement techniques. However, in addition to clearance determinations, clinicians must be able to recommend appropriate medication doses according to the clearance values, pharmacodynamic goals, and other individual concerns. This is important because the available drug dosing references are not written to be personalized for the patient in your care. Individual patients may have specific therapeutic goals or may be receiving different dialytic techniques or concomitant medications that could affect the plasma and tissue concentrations of drugs. The following sections will review drug dosing equations that use the clearance determinations from continuous renal replacement modalities (Table 27.6). These equations can also be used for dosing drugs in patients with chronic kidney disease. Additional information for drug clearance and dosing in chronic kidney disease can be found in several manuscripts and reviews. The equations will empower the clinician to calculate the plasma concentrations likely to result under given administration scenarios. In addition, the equations can be rearranged to solve for dose to enable the dosing revisions required to reach targeted plasma concentrations. The equations described in the following sections are applicable to drugs that are described by a one-compartment model.

**Intravenous Bolus**
Intravenous bolus administration implies an instantaneous administration of drug into the central compartment of the body. Many drugs (e.g., morphine, diphenhydramine) are administered as a direct intravenous bolus in the critical care unit. In addition, intravenous bolus administration can be used to provide a loading dose of medications and will be followed by an intravenous infusion. The maximal plasma concentration (Cp) after intravenous bolus administration is described by the dose and Vd (equation 27.9).

\[ \text{C}_p = \frac{\text{dose}}{\text{Vd}} \] (equation 27.9)

<td>( \text{Dose} = \frac{\text{C}_{\text{SS}} \times \text{Cl} \times \tau}{(S \times F)} )</td>
</tr>
</tbody>
</table>

*The equations are representative of one-compartment models.*

As shown in the equation, a good estimation of the Vd for the drug in the critically ill patient will suffice for determining concentration without respect to clearance. If the concentration is less than expected,
the Vd of the drug in the patient was higher than predicted by literature values. The equation can be rearranged to inform about the Vd in the particular patient. Subsequent intravenous bolus doses can be modified according to the actual Vd to achieve a targeted peak plasma concentration. The decline of the plasma concentration after intravenous bolus administration will suggest whether the drug follows a one-, two-, or three-compartment model.

**Intravenous Infusion (during infusion)**

Although an intravenous bolus is straightforward, infusions are more complicated. For intravenous infusions, it must be realized that clearance processes during the infusion will affect the obtained concentration in the plasma. The plasma concentration (Cp) can be computed at any time point (t) during the intravenous infusion according to equation 27.10, considering the rate of infusion (Ko), total body clearance (Cl), and amount remaining as defined by the term $1 - e^{-ke*t}$.

\[
C_p = \frac{Ko}{Cl} \times [1 - e^{-ke*t}] \quad \text{(equation 27.10)}
\]

As suggested earlier, the total body clearance should be the sum of the residual renal, nonrenal, and renal replacement therapy clearance. The duration of the renal replacement therapy will further affect the clearance. This condition (equation 27.10) does not represent steady state. **Equation 27.10** will be helpful to use to determine where the plasma concentrations fall during an infusion and to calculate the infusion rates needed to achieve a targeted drug concentration.

**Intravenous Infusion (at steady state)**

The plasma concentration at steady state ($C_{pss}$) can be computed for drug therapy that requires an intravenous infusion according to **equation 27.11**, considering the rate of infusion (Ko) and total body clearance (Cl). Note that the amount remaining term is not included because, by definition, steady state would imply that the rate in equals the rate out.

\[ C_{pss} = \frac{K_0}{Cl} \] (equation 27.11)

This method can also be useful to determine rates of infusion needed given a known clearance and targeted \( C_{pss} \).

**Intravenous Infusion (at end of infusion)**

The plasma concentration at the end of an infusion (time is \( T \)) can be computed according to equation 27.12, considering the rate of infusion (\( K_0 \)), total body clearance (\( Cl \)), and amount remaining term \( (1 - e^{-ke*T}) \) that incorporates the end of infusion time term (\( T \)).

\[ C_p = \frac{K_0}{Cl} \times [1 - e^{-keT}] \] (equation 27.12)

This equation will be helpful to determine where the plasma concentrations fall at the end of one infusion rate in order to guide changes to infusion rates for subsequent doses to achieve a targeted drug concentration.

**Intravenous Infusion (after end of infusion)**

Finally, the plasma concentration at any time point after the end of an intravenous infusion (time) can be computed according to equation 27.13, considering the concentration at the end of the infusion (\( C_p \) at \( T \)) and the loss of drug between the end of the infusion and \( T \) \( (e^{-ke*[\text{time}-T]} \)).

\[ C_p = C_{p \text{ at time } T} = e^{-ke*[\text{time}-T]} \] (equation 27.13)

**Extravascular Route**

The calculation of the plasma concentration after administration of a drug by the extravascular route is more complicated (equation 27.14). It requires the bioavailability term (\( F \)), dose, \( Vd \), and rate constants for elimination (\( Ke \)) and absorption (\( ka \)).
If the usual condition of the absorption rate being faster than the elimination rate is not met, the drug is said to have flip-flop pharmacokinetics. Given the potential absorption issues in critical care patients, clinical scenarios whereby flipflop pharmacokinetics are shown are highly likely.

At steady state, an extravascular dose can be calculated as shown in equation 27.15.

\[
C_p = \frac{F \times \text{dose} \times K_a}{V_d (K_a - K_e)} \times \left[ e^{-k_e t} - e^{-k_a t} \right]
\]

(equation 27.14)

In equation 27.15, the numerator is the product of the concentration in plasma at steady state (Cpss), total body clearance (Cl), and dosing frequency (Tau), whereas the denominator is the product of the salt form of the drug (S) and bioavailability (F).

More advanced pharmacokinetic modeling and simulation using population approaches are warranted to fully understand the differences in pharmacokinetics in discrete populations within the ICU. In addition, population modeling techniques enable the determination of patient, clinical, and renal replacement therapy covariates that could affect pharmacokinetic parameters and interindividual variability.\(^{59}\)

IMPLICATIONS OF DRUG DOSING ON PHARMACODYNAMIC EFFECTS

It has been suggested that despite attention to adjustments of drugs in patients receiving renal replacement therapies, patients with infections who are receiving antibiotics often have inadequate outcomes.\(^{60,61}\) Because of variations in drug clearance by renal replacement therapies, it is highly recommended that clinicians treat infections aggressively, especially during the early phase of treatment, using loading doses to reach targeted plasma concentrations sooner. For antibiotics, the targeted plasma concentrations should consider the
desired concentrations at the infection site. It is necessary for clinicians to consult their local laboratory to obtain susceptibility data (minimum inhibitory concentrations [MICs]) for antibiotics to ensure that targeted concentrations are adequate. Clinicians also need to identify whether the selected antibiotics have time- or concentration-dependent killing. For drugs that have time-dependent killing, previous data analyses have suggested that maximal bactericidal effects occur when concentrations above the MIC are obtained for a defined percentage of the dosing interval: for cephalosporins, about 60%–70%; penicillins, 50%; and carbapenems, 40%. These targeted times have been used as pharmacodynamic measures for therapy outcomes. In the study by Seyler et al., 90% of patients receiving antibiotic therapy (meropenem, piperacillin/tazobactam, cefepime, or ceftazidime) had plasma concentrations deemed adequate for concentration breakpoints of Enterobacteriaceae, but inadequate for most other microorganisms. According to Seyler et al., the dosing ranges suggested for the antibiotics mentioned previously in critical care patients receiving renal replacement therapies would have resulted in poor pharmacodynamic responses given the percentage of the antibiotic dosing interval in which drug concentrations are greater than the MIC.

These data analyses suggest that clinicians should use the combined pharmacokinetic-pharmacodynamic simulation tools available in many commercial pharmacokinetics software packages to more accurately estimate how dosing recommendations may affect pharmacodynamic outcomes. Strategies proposed during continuous renal replacement therapies to optimize the attainment of adequate concentrations of antibiotics with time-dependent killing include continuous or prolonged infusions, shorter dosing intervals, supplemental dosing, and weight-based dosing. For antibiotics that have concentration-dependent dosing (e.g., aminoglycosides, colistin, daptomycin, fluoroquinolones, linezolid, macrolides, metronidazole, vancomycin), strategies such as loading doses, extended dosing intervals, and weight-based dosing have been proposed to optimize pharmacodynamic outcomes. A paucity of literature exists for other
classes of drugs and pharmacodynamic outcomes in patients undergoing continuous renal replacement therapies.

**CLINICIAN DOSING AND OUTCOMES**

Despite clinicians providing dosing consultations for drugs in patients receiving renal replacement therapies, there are limited publications that show outcomes. One publication reported more than 180 recommendations for dosing adjustment of antimicrobials in critical care patients. Changing continuous renal replacement therapy conditions was reportedly the most common reason for dosing errors, showing the need to adequately monitor for these changes and incorporate them into clearance and drug dosing equations. Of importance, clinician dosing recommendations had positive clinical outcomes, including reduced length of stay in the ICU by 3 days as compared with a control group not receiving targeted recommendations. Another recent publication evaluated prescribing patterns of antimicrobials in patients receiving sustained low-efficiency dialysis. Results indicated that antimicrobial under-dosing was a predominant problem, with failures to reach clinical cures. These data show the potential for the positive impacts clinicians can have on outcomes in patients receiving renal replacement therapies.

**ONGOING CONSIDERATIONS FOR CONTINUOUS RENAL REPLACEMENT THERAPIES**

According to the available published data for the pharmacokinetics of drugs during continuous renal replacement therapy, it is clear that most evaluated drugs have been antibiotics. Given the polypharmacy in the ICU population, future studies should assess pharmacokinetic alterations and dosing guidance for other classes of drugs. Most published research evaluating drug pharmacokinetics during renal replacement has focused on adults. However, given the increased frequency of these therapies in the pediatric population and the inherent pharmacokinetic differences between adult and pediatric
patients, future research should include this patient subgroup as well.

Continuous renal replacement therapies have been in clinical use since the 1990s. However, the therapy conditions have evolved over time with new hemofilters composed of different materials and higher effluent rates. It is necessary to note the therapy conditions in published research in order to determine the relevance to individual patients today. It may be necessary to recalculate the expected clearance for a drug of interest according to the differences in effluent rates in the past versus the present. Pharmacokinetic-pharmacodynamic modeling and simulation can assist with achieving targeted concentrations and clinical outcomes.

Finally, given the widespread use of continuous renal replacement therapies, it is now necessary to provide education and experiential training to students and clinicians who train or practice in the critical care setting.

---

**PLASMAPHERESIS**

Plasmapheresis is a continuous flow procedure that involves the extracorporeal separation of plasma from other blood components through intravenous access. The plasma is discarded and exchanged with a physiological replacement fluid that varies depending on the clinical scenario and typically contains albumin or fresh frozen plasma. Replacement fluid is necessary to maintain oncotic pressure and intravascular blood volume in order to avoid hypovolemic shock. Replacement fluid in conjunction with the patient’s blood and cellular components is returned to the patient through the intravenous access.

There are many clinical indications for the use of plasma-pheresis. Disease indications include thrombotic thrombocytopenic purpura, myasthenia gravis, acute/chronic inflammatory demyelinating polyneuropathy, acute antibody-mediated rejection related to a variety of solid organ transplant types, and other autoimmune processes. In addition, plasmapheresis has been reported to be effective for the treatment of medication overdoses and venomous exposures. Apart from the intended use of plasmapheresis for the treatment of
medical conditions and toxicological problems, there is an unintended effect of plasmapheresis on the loss of prescribed medications. The impact of plasmapheresis on the pharmacokinetics of medications commonly prescribed in the ICU setting is not insignificant. There continues to be a paucity of evidence-based guidelines on the impact of plasmapheresis on drug clearance.

Limited studies in the literature report formal pharmacokinetic evaluations of drugs during plasmapheresis. In 2007, Ibrahim et al. described the existing limitations of the available published literature on this topic including (1) heterogeneity of plasma exchange procedures with respect to the duration, volume, and type of replacement fluid used; (2) lack of uniformity in plasma sampling times for pharmacokinetic evaluation among studies, and the relationship of this sampling to initiation of plasmapheresis; (3) use of different analyses to ascertain removal such as declines in drug plasma concentration versus the total quantity of drug removed during plasmapheresis; (4) statistical flaws; and (5) inappropriate extrapolations between patient populations (e.g., adult data extrapolated to neonates).

**DRUG CHARACTERISTICS FOR CLEARANCE BY PLASMAPHERESIS**

There are specific drug- and plasmapheresis-dependent factors that influence the likelihood of a drug being cleared by this extracorporeal technique (Table 27.7). To provide a framework for the extent of solute removal during plasmapheresis, one study reported that a single exchange of 1 plasma volume (about 3 L in a 70-kg adult patient) removes around 63% of all solutes in the plasma, and an increase to a 1.5 exchange volume removes about 78% of solutes. Solute elimination by plasma exchange is passive and described by linear kinetics. The time between the drug administration and plasmapheresis initiation is considered to be the most important and critical factor affecting drug removal. Several early studies evaluating the disposition and removal of ceftriaxone, ceftazidime, phenobarbital, vancomycin, gentamicin, thyroxine, and aspirin reported increased drug
removal when plasmapheresis was initiated immediately or shortly after drug administration. These data are consistent with more recent findings such as those described for cefepime removal by plasmapheresis. Ibrahim et al. also reported data showing that 75% of mycophenolate mofetil was recovered in the volume of plasma removed when it was concurrently administered by intravenous infusion during the plasmapheresis procedure.

Drugs with a higher degree of protein binding have enhanced removal during plasmapheresis. In general, a drug whose protein binding is greater than 80% will be removed by plasmapheresis. It
is suggested that for a drug bound to albumin, a linear relationship exists between the fraction eliminated during the plasmapheresis session and the fraction of the drug present in the extracellular fluid. Plasma proteins and bound drugs are removed in tandem with fluid in plasmapheresis. Of importance, this scenario is contrary to what is known about drug protein binding and clearance during extracorporeal dialysis techniques. During dialysis procedures (intermittent or continuous), drugs with increased protein binding are not significantly removed. The unbound fraction of drugs is cleared through dialysis procedures (as described earlier in this chapter).

Drugs with a lower Vd (less than 0.2 L/kg) are more likely to be removed by plasmapharesis. This is intuitive because drugs must be in the plasma compartment to be eliminated by plasmapheresis. A drug with increased Vd has reduced clearance by plasma exchange. Calculating patient-specific Vd values for medications will enable an estimate of total body drug stores. This method is the most stringent for determining the drug fraction eliminated during plasmapheresis. Single-dose drug studies of plasmapheresis are limited because the Vd after a single dose may vary from the Vd at steady state and is one of the limitations of many of the published studies. Hydrophilic drugs with small volumes of distribution and high protein binding would be predicted to be cleared, especially if administered around the time of the plasmapheresis procedure. However, lipophilic drugs have large Vd and would not be expected to have significant clearance by plasmapheresis. For example, voriconazole, a lipophilic drug with a large Vd (4 L/kg) and moderate protein binding (58%), was not significantly removed by plasmapheresis.

**PLASMAPHERESIS CONDITIONS AND DRUG CLEARANCE**

Several plasmapheresis-specific factors are implicated in drug clearance including the duration of the plasmapheresis procedure, need for successive plasmapheresis sessions, volume of plasma removed, and type of replacement fluid used (Table 27.8).

*a* This is not a comprehensive list of medications. A more comprehensive list can be found in Ibrahim RB, Balogun RA. Medications in patients treated with therapeutic plasma exchange: prescription dosage, timing and drug overdose. Semin Dial 2012;25:176-89.

t½ = half-life.

Most commonly, plasmapheresis sessions last 1–3 hours. The duration of the sessions can vary depending on the patient’s hemodynamics during exchange of the desired plasma volume and the overall therapeutic goals. Although some drugs have a large Vd and will not be removed by plasmapheresis, others that are highly protein bound will have increased removal, as previously discussed. An extended duration of each session may result in increased drug removal. It is, however, important to realize that although some drugs such as β-blockers are heavily removed by plasmapheresis, blood concentrations do not correlate with their biologic effect. As such, removal by plasmapheresis may not always predict changes in pharmacodynamics. However, out of an abundance of caution, it is
recommended that drugs with a small Vd and high degree of protein binding be administered after the plasmapheresis session.

In some clinical scenarios, several plasmapheresis sessions may be required, often on a daily basis, depending on the intended outcome. As discussed previously, waiting to dose drugs with small distribution volumes and increased protein binding until after the plasmapheresis session is complete may allow for enhanced benefits from the therapies.

Because dilution of plasma occurs secondary to the administration of replacement fluid, the targeted substances of interest cannot completely be removed from the circulation. For example, for each 1–1.5 plasma volume exchanged, about 60%–70% of the substances present in the plasma at the start of that plasma volume will be removed. As additional plasma volumes are exchanged, the absolute amount removed becomes lower, although the removal of a fixed 60%–70% still occurs. For this reason, routine practice is to exchange only 1–1.5 plasma volumes during a single plasmapheresis session. Plasmapheresis volumes beyond 1.5 plasma volumes remove smaller, less clinically important amounts of pathologic substances present in the plasma while prolonging the procedure and exposing patients to more replacement fluid with an increasing risk of complications. Similar to the removal of pathologic substances, plasma volume can also affect the removal of drug solutes.

The composition of the replacement fluid influences the effects of plasmapheresis on the patient. It is known that about one-third of the replacement fluid administered at the beginning of a session will be present by the end, with the other two-thirds removed. Administering plasma as a replacement fluid at the beginning of a session exposes the patient to blood products without additional clinical benefit. The most commonly used replacement fluid is 5% albumin in physiological saline. This fluid mixture has several advantages because it decreases the risk of disease transmission from the use of blood products and transfusion-related reactions such as acute lung injury. This specific replacement fluid has a higher oncotic pressure than plasma and thus may result in expansion of the intravascular volume.
concentrations in the replacement fluids may affect drug clearance through protein binding.

---

**DRUG PHARMACODYNAMICS WITH PLASMAPHERESIS**

As mentioned previously, plasma concentrations of drugs and therapeutic proteins do not always correlate with clinical effects. Therefore, plasmapheresis may not alter the biologic effect of a drug despite reducing the plasma concentration. This scenario has been shown for rituximab, a monoclonal antibody used for the treatment of a variety of conditions. Rituximab has a moderate Vd (3.1 L), no protein binding, and a half-life of 9–70 days. Despite these pharmacokinetic parameters, significant removal of rituximab is seen when it is dosed within 24 hours of a plasmapheresis session. The main mechanism for rituximab removal by plasmapheresis is unknown but is thought to be related to the removal of the therapeutic antibody or antibody complexes and resulting inflammatory cytokines, or the transient depletion of complement. However, an assessment of pharmacodynamic markers (peripheral CD19 B cells and ADAMST12 immunoglobulin G, and increased ADAMST13 activity) has suggested that the drug response was unaltered. Given this example, it can be concluded that the removal of therapeutic proteins by plasmapheresis does not necessarily translate to a loss of pharmacologic effects. The optimal timing between drug administration and plasmapheresis initiation for different drugs remains ill defined, and the correlation between drug pharmacokinetics and clinical outcomes requires further study.

Plasmapheresis may have effects on drugs because of the clearance of other circulating components necessary for drug effectiveness. Plasmapheresis is known to reduce levels of antithrombin III, and can therefore have an effect on achieving therapeutic anticoagulation. A study evaluating anti-factor 10a activity during plasmapheresis found decreased anti-factor 10a and a 40% loss in a patient receiving low-molecular-weight heparin. This is thought to be related to the extraction of antithrombin III alone or the complex
of heparin and antithrombin III. Patients on plasmapheresis who require simultaneous anticoagulation with heparin may require higher doses to achieve therapeutic effects.

Patients receiving plasmapheresis often have other comorbidities that can influence the pharmacokinetics of drugs. For example, acute renal or hepatic failure can alter pharmacokinetics, independent of plasmapheresis. Clinicians should review the characteristics of prescribed drugs (protein binding, Vd) before plasmapheresis initiation so that they can be aware of the medications that should be closely monitored for decreased efficacy secondary to increased clearance. Ibrahim et al. have published two excellent reviews from the literature (case reports and randomized studies) on the impact of plasmapheresis on drug removal. Table 27.8 is a summary of drug clearance by plasmapheresis. Finally, if the pharmacokinetic and pharmacodynamic effects of plasmapheresis on the drug are not well described, administration of drugs after a plasmapheresis session remains a viable and conservative approach. Therapeutic drug monitoring should also be considered when available.

**EXTRACORPOREAL MEMBRANE OXYGENATION**

Extracorporeal membrane oxygenation (ECMO) is a type of extracorporeal life support and, depending on its configuration, can be used to provide oxygenation, carbon dioxide removal, and/or perfusion to vital organs for days to weeks in critically ill patients with lung and/or cardiac dysfunction. Its use spans a wide variety of populations, including neonates, children, adolescents, and adults. The first successful use of ECMO was in 1972, but initial enthusiasm was dampened when a randomized controlled trial of ECMO for adult acute respiratory distress syndrome (ARDS) was terminated because of futility. Although there have been some advances in technology, enthusiasm for this technique in adults has been renewed because of recent randomized and cohort studies of patients with severe ARDS, and in particular H1N1-related ARDS where reductions in mortality were reported.
The two separate modes of ECMO are venovenous and venoarterial. Venovenous ECMO is used for isolated respiratory failure, and its use increased dramatically in adults during the H1N1 influenza outbreak. In this mode, systemic blood flow and pressure are the result of native cardiac function unrelated to extracorporeal flow. Venoarterial ECMO is used for isolated cardiac failure or combined cardiopulmonary failure. Systemic flow is a combination of that established by the extracorporeal circuit plus the amount of blood passing through the native heart and lungs. Systemic oxygen and carbon dioxide concentrations are determined by a mix of blood passing through the lungs and heart and oxygenated blood that is reinfused from the circuit into the arterial circulation.

**ECMO Components**

Several circuit components are known to affect drug pharmacokinetics. A clear understanding of each of the circuit components, including the tubing, oxygenator, type of circuit (roller vs. centrifugal pump), and venous reservoir, is necessary to understand how they may affect drug pharmacokinetics. Several excellent reviews have been published that describe these components and their function. Figure 27.7 depicts the standard ECMO circuit setup.

The purpose of the pump is to push blood through the oxygenator and back to the patient. Flow in the centrifugal pump is dependent on the blood volume from the patient, systemic vascular resistance, size of the cannula, and pump speed. The main advantage of the centrifugal pump is that it creates less negative pressure on the blood, and therefore less hemolysis. Flow in the roller pump depends on the size of the tubing in the raceway, occlusion pressures of the rollers, pump speed, and blood volume. One of the major disadvantages of the roller pump is increased hemolysis and continued rotation of the pump independent of blood volume or air entrapment.

The two main devices used for gas exchange in the ECMO circuit are the silicone membrane oxygenator and the hollow fiber oxygenator. The hollow fiber oxygenator has major advantages, including priming
that is easy and fast, presence of a coating that reduces the risk of clot formation, smaller surface area to reduce platelet activation and inflammation, and lower pressure gradient across the membrane to reduce shear stress on the red blood cells and subsequent hemolysis.

Different types of ECMO tubing exist, each with different components, and are beyond the scope of this chapter. However, remember that each of these tubing types can influence drug pharmacokinetics in patients on ECMO.

An ECMO circuit may also include a venous reservoir or bladder located on the venous line before the pump and serves as an air bubble trap and volume buffer as it sits at the lowest point on the ECMO circuit. Clot formation in the reservoir poses a significant risk. Pooling of medications may occur in the venous reservoir, especially if the specific gravity of the medication is less than that of blood. For this reason, it is recommended that medications be administered in the circuit at a location after the reservoir.98 Many centers no longer use a venous reservoir as part of the ECMO circuit.

**Factors Responsible for Alterations in Drug Pharmacokinetics in ECMO**

Extracorporeal membrane oxygenation can alter the pharmacokinetics and pharmacodynamics of medications for a variety of reasons in a population (e.g., critically ill patients) already known to have altered drug pharmacokinetics. The addition of ECMO increases the degree of systemic inflammation because of the interaction between the patient’s blood and the artificial membranes, hemodilution, transfusions, organ dysfunction, and renal replacement therapy.99,100 Extracorporeal membrane oxygenation treatment can lead to drug sequestration and changes to Vd and clearance. The addition of continuous renal replacement therapy to the ECMO circuit (Figure 27.7) can result in further changes to drug pharmacokinetics (as described earlier in this chapter). Although the body of literature on the effects of ECMO on drug clearance is growing, data are currently insufficient to make meaningful recommendations for drug dosing adjustments.101 Ongoing
studies continue to investigate altered pharmacokinetics and related outcomes for a variety of drugs commonly administered to patients requiring ECMO.\textsuperscript{102,103} These studies fall into three general categories: in vitro studies related to the physiochemical properties of drugs (e.g., drug binding to ECMO circuitry), classical pharmacokinetic studies, and clinical trials evaluating outcomes.\textsuperscript{89}

\textbf{Figure 27.7} Standard extracorporeal membrane oxygenation (ECMO) circuit.

Venous blood drains from the patient and passes through a venous saturation sensor and a bladder before being pumped to the oxygenator/heat-exchanger device. The oxygenated warmed blood passes the ECMO circuit bridge before infusing back into the patient into the arterial (venoarterial) or venous (venovenous) system. There are many infusion and access ports, as well as pressure and flow monitors, along the way.

\textit{CRRT} = continuous renal replacement therapy.
Drug Sequestration and Influence of ECMO Circuit Components and Drug Characteristics

Drug sequestration on ECMO is well known but poorly characterized. It is influenced by specific drug properties, including molecular size, degree of ionization, lipophilicity, and plasma protein binding.\textsuperscript{104} Sequestration is a function of binding to a biosynthetic surface. The most common biosynthetic surface is the standard polyvinyl chloride tubing. In addition, there are a variety of other coated tubing types, including Maquet Safeline (synthetic immobilized albumin), Maquet Softline (heparin-free biopassive polymer), Maquet Bioline (recombinant human albumin plus heparin) by Maquet Cardiopulmonary AG (Hirrlingen, Germany), Terumo X Coating (poly2methoxylacrylate) by Terumo Cardiovascular Systems Corporation (Ann Arbor, MI), and Medtronic Carmeda (covalently bonded heparin) and Medtronic Trillium (covalently bonded heparin) by Medtronic (Minneapolis, MN). Sequestration can vary depending on the circuit components (pump, oxygenator, tubing, venous reservoir), circuit priming, and age of the circuit.\textsuperscript{105,106} Most of the available data on drug disposition have been derived from neonatal studies using older-generation ECMO circuits.\textsuperscript{107} In these studies, significant sequestration by the ECMO circuit was observed and was dependent on the physiochemical properties of drugs and the type and age of the circuits used.\textsuperscript{104,107,108}

In an adult ex vivo model of ECMO using contemporary circuitry, Shekar et al. hypothesized that lipophilic and protein bound drugs have enhanced sequestration in ECMO circuits.\textsuperscript{109} The authors used four identical ECMO circuits comprising centrifugal pumps and polymethylpentene oxygenators to investigate the influence of plasma protein binding on drug disposition. Drug recovery was defined as the amount of drug recovered from the ex vivo circuit at the end of the study and after accounting for sequestration. Ceftriaxone, ciprofloxacin, linezolid, fluconazole, caspofungin, and thiopentone were selected for
evaluation on the basis of lipophilicity and protein binding values. Lipophilicity (log P) and protein binding values for these drugs appear in Table 27.9. The circuit conditions (oxygen tension, temperature, activated clotting times, pH) were kept stable in order to discern differences in sequestration related to drug characteristics. Study drugs were injected post-oxygenator as a single bolus dose, with doses selected on the basis of producing concentrations that were similar to expected clinical concentrations. Larger doses were chosen for drugs having high protein binding in order to achieve concentrations that were similar to clinical concentrations. Equivalent doses of drugs were injected into four polypropylene jars containing fresh human whole blood in order to serve as study controls and for stability testing. Serial blood samples were collected from the ECMO circuits and control reservoirs over 24 hours. Drugs with a significant decrease in plasma concentration at 24 hours had a high degree of protein binding (greater than 80%), were highly lipophilic (log P greater than 2.3), or both, with a recovery of less than 20%. However, meropenem, a drug with a low degree of protein binding (2%) and hydrophilic (log P -0.6), had a very low plasma concentration remaining at 24 hours, which was attributed to its instability at physiological temperature. This situation highlights the need to study and identify the impact of ECMO on the sequestration of thermolabile medications. Despite this robust study, it remains unclear whether protein binding and lipophilicity definitively have an additive effect on drug sequestration in the circuit. In addition, drugs with a similar lipophilicity but different protein binding can have variable recovery from the circuit, suggesting that protein binding determines circuit drug sequestration.

</tr>
</tbody>
</table>
A significant loss of ampicillin, a hydrophilic drug (log P -2.0) with low protein binding (15%–25%), was reported in ex vivo blood primed circuits compared with crystalloid primed circuits. This suggests that ECMO circuits can bind blood proteins and drugs, and it is unclear whether there is a competitive binding between them, and if so, whether this phenomenon is concentration-dependent.

The mechanisms that lead to circuit sequestration of highly protein bound drugs are unclear. In ex vivo neonatal circuits, 80% of fentanyl (85% protein bound, log P 3.9) was sequestered in the absence of an oxygenator, and an additional 6% sequestration occurred when the oxygenator was added. It has been postulated that circuit sites that bind albumin and other proteins on priming or after the passage of blood lead to binding of administered drugs that have high protein binding. In a recent study evaluating different circuit types, there were significant differences in drug recovery rates between roller and centrifugal pumps, respectively, for fentanyl (0.4% vs. 34%) and midazolam (0.6% vs. 63%). Similar to fentanyl, midazolam is 92% protein bound and has a log P value of 3.9. Age of the ECMO
circuit can also influence drug sequestration. Midazolam sequestration in the first 10 minutes in a used ECMO circuit was lower than in a new ECMO circuit (4.1% vs. 26.1%, p = 0.0004), but this difference disappeared after 180 minutes. For both midazolam and fentanyl, there was a failure to reach steady state, and ongoing drug losses suggest the presence of a greater amount of binding sites within the ECMO circuit for these drugs than for other evaluated compounds. This study, however, did not identify where the loss of drugs occurred. Although all drugs are clinically administered before the oxygenator in the circuit to decrease the risk of air embolus, given the results, it can be hypothesized that fentanyl and perhaps other highly lipophilic drugs have less therapeutic effectiveness when administered pre-oxygenator in the ECMO circuit. Hence, these drugs should be administered directly to the patient to minimize sequestration.

It is known that drug adsorption by polymers (silicone and rubber) is related to lipophilicity. As the total adsorptive capacity is linked to total surface area, ECMO circuits with larger membrane oxygenators and longer tubing may result in more adsorption. It has been reported that polyvinyl chloride tubing with newer surface coatings such as the Maquet tubing (including Bioline) led to a decrease in morphine concentration in the circuit to 51% of baseline compared with 35% of baseline in other types of tubing, suggesting that adsorption by certain tubing types is significantly reduced.

Several unanswered questions remain regarding sequestration of drugs during ECMO. Controversy currently exists over whether new or old circuits have more drug sequestration, with studies showing significant variability. It remains unclear how fast saturation occurs for the protein and drug-binding sites in the ECMO circuit. The impact of competitive binding to blood proteins and circuit components from administration of concomitant drugs also remains unknown. When dye was administered to the venous limb of the circuit, it pooled at the loop of the reservoir. Newer types of reservoirs such as the collapsible Better Bladder (Circulatory Technology, Oyster Bay, NY), which is vertically oriented, may decrease this pooling by regulating forward flow through the ECMO pump.
In summary, the circuit loss of a drug through sequestration may represent a balance between the binding to the circuit components and the extent of drug protein binding. In addition, critically ill patients can have reductions in serum proteins that can influence protein binding of drugs in addition to the effects of binding to the circuit. Sequestration of drugs in the circuit may have implications in both choice and dosing of particular drugs during ECMO. The circuit may also release the sequestered molecules once a drug infusion is ceased. This situation is unpredictable and may prolong the pharmacologic effect in an undesirable manner. Interpatient variability inherent to critically ill children and adult patients contributes to altered pharmacokinetics observed on ECMO. Therefore, therapeutic drug monitoring is highly recommended, when available. It is also recommended to refer to routine drug dosing handbooks and recent ECMO literature for information pertaining to drug protein binding and Vd information and factors responsible for ECMO clearance.\textsuperscript{103,109,115}

\section*{VOLUME OF DISTRIBUTION}

Volume of distribution is the theoretical volume of fluid into which the total drug administered will have to be diluted to produce a concentration equal to that observed in plasma. It has been suggested that ECMO represents another pharmacokinetic compartment, similar to extra-corpooreal dialysis techniques. Extracorporeal membrane oxygenation can lead to a SIRS (systemic inflammatory response syndrome) that increases the Vd, resulting in low serum concentrations and therapeutic failure (Figure 27.8).\textsuperscript{101} The inflammatory response can down-regulate CYP enzymes in the liver and increase the Vd within the extracellular fluid.

Extracorporeal membrane oxygenation alters the Vd of medications (Table 27.10).\textsuperscript{101} The circuit may lead to a doubling in the patient’s extracellular fluid volume. This effect is much more pronounced with drugs that have a small Vd and for smaller patients. Extracorporeal membrane oxygenation circuit priming volumes in a child varies from 200 to 400 mL, and the circulating blood volume of an infant is 80–85
mL/kg. The dilutional effect of the circuit prime is exacerbated by the ongoing intravenous fluid requirements in the critically ill patient and by requirements for repeat blood and blood product transfusions. The degree to which ECMO itself expands the extracellular fluid compartment is debatable, and an increased drug Vd may be the result of the disease process rather than or in addition to ECMO. The prime and multiple transfusions dilute the plasma proteins and can result in decreased drug binding, increased free concentration of drug, and an apparent increase in Vd. Additional effects on plasma proteins during ECMO include binding of protein by heparin and potential denaturation of proteins passing through the membrane oxygenator. The large surface area of oxygenators can affect the Vd and drug concentrations. Dagan et al. examined circuits and showed that there was a significant decrease in drug concentration after flow through the oxygenator. They found that phenytoin concentrations in the circuit decreased by 43%, whereas vancomycin and morphine decreased by 36%, phenobarbital by 17%, and gentamicin by 10%. In circuits that had been used for 5 days, the drug concentrations decreased much less: morphine by 16%, vancomycin by 11%, and phenobarbital by 6%. This suggests saturation of the binding sites over several days.
Figure 27.8 Impact of critical illness, inflammation and ECMO on drug pharmacokinetics.

Impact of critical illness, inflammation, and extracorporeal membrane oxygenation on drug pharmacokinetics.

CO = cardiac output; ECMO = extracorporeal membrane oxygenation; SIRS = systemic inflammatory response syndrome.

Table 27.10 Impact of Pharmacokinetic (PK) Changes During ECMO and Clinical Implications
Several other important factors are known to increase drug Vd, including hemodilution from priming solutions at ECMO initiation, ongoing blood product transfusions, pH alterations that affect protein binding and therefore distribution, and administration of volume to maintain circuit flows.\(^\text{107}\) Although hemodilution can often enhance the pharmacokinetic effect of highly protein bound drugs by increasing the unbound fraction, redistribution of free drug into the tissues may result in a lower serum concentration.\(^\text{107}\)

Much of the ECMO data evaluating Vd originate from the neonatal population. This population has a higher proportion of total body water and less adipose tissue. As a result, neonates will have a higher Vd for hydrophilic drugs (\(\beta\)-lactams and aminoglycosides) and a lower Vd for lipophilic drugs (fluoroquinolones and macrolides) relative to adults. There is also decreased protein binding in neonates, resulting in increased unbound drug concentrations and Vd.\(^\text{116}\) These physiological alterations limit the use of neonatal pharmacokinetic data to guide drug
dosing in critically ill adults requiring ECMO. Table 27.10 summarizes the pharmacokinetic changes during ECMO and clinical implications.\textsuperscript{101}

**DRUG CLEARANCE**

Several indirect mechanisms lead to decreased drug clearance during ECMO. Preceding hypoxia and hypoperfusion may lead to a kidney insult and decrease in renal clearance. Extracorporeal membrane oxygenation can result in altered organ perfusion most prominently by the lack of pulsatility, even though tissue oxygen delivery may be adequate. However, a comparison of the half-life for gentamicin in infants who received either venoarterial ECMO or venovenous ECMO was no different.\textsuperscript{117} Alterations in regional liver blood flow may also affect the clearance of drugs, especially those with a high extraction ratio. Decreased pulmonary blood flow during venoarterial ECMO may affect the sequestration and metabolism of many sedative and analgesic drugs by the lungs.\textsuperscript{118} Drug removal by the ECMO circuit may reduce the bioavailability of the first dose as well as the overall clearance.\textsuperscript{108} Decreased clearance predisposes the patient to drug toxicity, especially for drugs with a narrow therapeutic window.

The clearance of a drug is also directly affected by ECMO. Clearance can be influenced by the degree to which ECMO affects bound or unbound drug concentrations. Drug adsorption to the pump/tubing and oxygenator can also result in clearance alterations. When the ECMO circuit is changed, there can be a rapid alteration in drug concentration because the binding sites are no longer saturated, which can affect clearance. Another consideration is whether the drug is administered in the circuit or directly to the patient. When drugs are administered directly in the circuit, there can be differences in drug concentration depending on whether dosing location is before or after the oxygenator.

**RENAL REPLACEMENT THERAPY**

Discussion of renal replacement therapy during ECMO is complex.
because of the variability in techniques, including where the renal replacement circuit is located in relation to the oxygenator. This high degree of variability in techniques emphasizes the need for therapeutic drug monitoring where available, especially because adding another extracorporeal circuit can further affect the Vd, sequestration, and clearance of drugs.

Section 6

Liver/Gastrointestinal
LEARNING OBJECTIVES

1. Define acute liver failure (ALF) and describe the epidemiology of ALF.

2. Describe the pathophysiology of ALF.

3. Describe and contrast etiologies of ALF including acetaminophen, idiosyncratic drug-induced ALF, and viral infections.

4. Explain different prognostic indicators used in ALF.

5. Describe clinical presentation of patients presenting with ALF.

6. Define the mechanism of action of acetylcysteine in the management of acetaminophen toxicity.

7. Summarize the four grades of encephalopathy.

9. Identify the most common infectious pathogen classes in patients with ALF.

10. Describe nonpharmacologic interventions in the management of ALF.

11. Describe general principles of hepatic drug clearance and
potential mechanisms of altered drug disposition in ALF.

12. Apply principles of altered drug disposition in ALF in selecting and modifying pharmacotherapy in a patient with ALF.

### INTRODUCTION

Acute liver failure (ALF) is a rare form of severe liver disease, characterized by a rapid deterioration of liver function in individuals without known preexisting liver disease.\(^1\,^2\) ALF is associated with
substantial morbidity and mortality, often resulting in the need for life-
sustaining therapies and potential liver transplantation for definitive
treatment. Further, ALF can impact the pharmacokinetics of numerous
drugs. In this chapter, the pathophysiology of ALF is reviewed,
followed by an overview of ALF management, and general
recommendations for drug dosing in ALF.

DEFINITIONS
Acute liver failure represents a syndrome, rather than a specific
disease, and can have several causes that vary in outcome. In the
past, ALF has also been called fulminant hepatic failure or fulminant
hepatitis. A widely used definition for ALF is acute onset (illness less
than 26 weeks in duration) of coagulation abnormalities (commonly, an
international normalized ratio [INR] of 1.5 or greater) and any degree
of hepatic encephalopathy (which can be defined as any change in
mental status) in a patient without preexisting hepatic disease. Other
definitions have characterized ALF as development of hepatic
encephalopathy within 8 weeks of the first symptoms of liver disease
(of note, the key features of the definition are the same: hepatic
encephalopathy and symptoms of hepatic failure [jaundice,
coagulopathy] in the absence of chronic hepatic disease). Acute liver
failure can further be subdivided into categories on the basis of the
length of illness (Table 28.1); this subclassification can be useful in
identifying the etiology of ALF. More recently, the term acute liver
injury has been used to describe patients with severe liver injury (INR
of 2 or greater and AST [aspartate transaminase] greater than 10
times the upper limit of normal) with no evidence of encephalopathy.
It is important to differentiate ALF from “acute on chronic” liver failure
because the treatment and prognosis of each disease can differ
substantially. Acute on chronic liver failure is generally regarded as an
acute deterioration of preexisting, chronic liver disease that is usually
related to an identifiable precipitating event that may be unrelated to
the original cause of liver disease. Acute on chronic liver failure will not
be discussed at length in this chapter; however, the care of patients
with acute on chronic liver failure resembles that of patients with ALF.

**EPIDEMIOLOGY**

Acute liver failure is relatively uncommon in developed countries, with about 2,000–3,000 cases in the United States per year, and is most commonly seen in young adults in their third decade.\(^1\),\(^4\),\(^8\) The ALF Study Group collected data related to ALF epidemiology for almost a decade; during this time, 67% of ALF cases were in women, and the mean age was 38 years (range 17–79 years).\(^3\) Of note, the etiology of ALF has a geographic distribution: in North America and Western Europe, the primary causes are acetaminophen toxicity and idiosyncratic drug hepatotoxicity, whereas in Asia and developing nations, the primary causes are infectious (particularly hepatitis B virus and hepatitis E virus). Acute liver failure is often associated with a poor outcome. The mortality rate associated with ALF can exceed 40%–50%, depending on the etiology and type of care provided, and overall 1-year survival including patients receiving a transplant is about 65%.\(^1\),\(^9\),\(^10\) The primary causes of death in ALF are cerebral edema (as a result of increased intracranial pressure [ICP]), sepsis, and shock/multiorgan failure.\(^9\) Ultimately, orthotopic liver transplantation (OLT) is the only definitive therapy proved to be of benefit in patients with ALF who are unable to regenerate sufficient hepatocyte mass.\(^1\),\(^9\)

**PATHOPHYSIOLOGY**

Specific mechanisms of disease vary for different ALF causes. However, common to most etiologies is the presence of massive hepatocyte loss resulting in rapid loss of hepatic metabolic and immune function.\(^2\),\(^8\) The liver has the capacity to regenerate lost mass; however, ALF occurs when loss of hepatic cells exceeds the liver’s ability to regenerate.\(^11\) Precipitating factors for hepatocyte loss vary by etiology (see text that follows) and include both direct injury and immunologic injury.\(^12\) With respect to immunologic injury, innate immune-mediated injury is triggered early, which may be followed by adaptive
immune responses.\textsuperscript{12}

$^a$Symptom duration from onset of jaundice to hepatic encephalopathy.

The pattern of hepatocyte death may follow a pattern of necrosis, apoptosis, or both.\textsuperscript{11} Necrosis involves depletion of adenosine triphosphate (ATP), leading to cell lysis and secondary inflammation, whereas apoptosis is an ATP-dependent programmed cell death.\textsuperscript{11} Although once thought to be separate entities in ALF, necrosis and apoptosis may share initiating factors and signaling pathways and may thus occur as alternating patterns of hepatocyte destruction.\textsuperscript{11} Mitochondrial permeability transition (a process leading to mitochondrial swelling) may be a common event causing both patterns of hepatocyte destruction, where the pattern of death depends on whether ATP is depleted (necrosis) or preserved (apoptosis).\textsuperscript{11} Apoptosis may be the predominant mode of hepatocyte destruction in ALF caused by viral and toxic etiologies.\textsuperscript{12} Necrosis is often related to metabolic injury (leading to ATP depletion) and can be caused by ischemia/reperfusion and acute drug-induced hepatotoxicity.\textsuperscript{13}

The acute and massive loss of hepatocytes in ALF leads to the release of ammonia, alanine, lactate, and pro-inflammatory cytokines from the splanchnic circulation, including tumor necrosis factor alpha, interleukin (IL)-1 beta, and IL-6.\textsuperscript{10,12} This inflammatory response is likely key to the systemic inflammation associated with ALF. Furthermore, the systemic inflammation can contribute to cerebral
edema by decreasing cerebrovascular tone.\textsuperscript{10,12} Release of intracellular materials from hepatocytes may lead to the polymerization of proteins that impairs hepatic microcirculation.\textsuperscript{10} Increased gut permeability may lead to increased absorption of luminal endotoxin, which, in conjunction with reduced hepatic endotoxin clearance, can further propagate the condition of systemic inflammation.\textsuperscript{10}

Acute liver failure leads to a syndrome that may include many physiologic derangements, including hepatic encephalopathy, cerebral edema, coagulopathy, oliguria/acute renal failure, portal hypertension, acidosis, systemic vasodilation with hypotension, hypoglycemia, respiratory failure, and impaired platelet and white blood cell function.\textsuperscript{5,10} More than half of patients with ALF meet the criteria for systemic inflammatory syndrome.\textsuperscript{5} In short, the profound hepatic dysfunction associated with ALF often precipitates the development of multiple organ dys-function syndrome.\textsuperscript{10} As indicated previously, the primary causes of death in ALF are cerebral edema, sepsis, and shock/multiorgan failure.\textsuperscript{3,14} Other causes of death include cardiac arrhythmia/arrest, respiratory failure, and infection (bacterial and fungal).\textsuperscript{3,14} Of note, despite the high prevalence of coagulopathy in ALF, mortality secondary to hemorrhage is rare in ALF.\textsuperscript{3}

**ETIOLOGY**

The causes of ALF include several toxic, infectious, metabolic, and vascular insults to the liver.\textsuperscript{10} As indicated previously, the frequency of the various etiologies of ALF follows a geographic distribution. The most common etiology of ALF in North America and Western Europe is acetaminophen toxicity. In the ALF Study Group registry, acetaminophen accounted for almost 40% of all cases of ALF.\textsuperscript{14} Idiosyncratic drug reactions (nonacetaminophen, 13% of cases) and viral hepatitis (hepatitis A virus infections and hepatitis B virus infections, collectively 11% of cases), were the next most common causes.\textsuperscript{14} In contrast, viral infections (hepatitis A virus, hepatitis B virus, and hepatitis E virus) are the most predominant causes of ALF in the developing world.\textsuperscript{2} In up to 15% of ALF cases, there is no determinate
cause. Determining the etiology of ALF is important because this assists in determining the appropriate therapy, helps rule out contraindications to transplantation, and can help predict prognosis.

**Acetaminophen**

As indicated earlier, acetaminophen is the most common cause of ALF in developed countries, accounting for greater than 25,000 hospitalizations and 400–500 deaths per year in the United States.\(^3\),\(^16\) It is likely that some cases of ALF with no recognizable cause may also be attributed to acetaminophen toxicity because acetaminophen adducts (produced by the binding of an active acetaminophen metabolite to cysteine residues) have been detected in some of these cases.\(^17\),\(^18\) Acetaminophen-related ALF is dose related. At therapeutic doses, greater than 90% of an acetaminophen dose is metabolized in the liver by a combination of glucuronidation and sulfonation (with the resulting metabolites excreted in the urine), about 2% of a dose is excreted unchanged in the urine, and 5%–10% of the dose is metabolized by cytochrome P450 (CYP) 2E1.\(^16\) The metabolism of acetaminophen by CYP2E1 results in the formation of N-acetyl-p-benzoquinone imine (NAPQI), an extremely reactive metabolite.\(^19\) At normal acetaminophen doses, the small amount of NAPQI that is formed is rapidly conjugated by hepatic glutathione and excreted in the urine. At supratherapeutic doses, sulfation and glucuronidation pathways become saturated, and more acetaminophen is metabolized to NAPQI by CYP2E1, eventually resulting in the depletion of hepatic glutathione.\(^16\),\(^19\) When hepatic glutathione stores are depleted by about 70%–80%, NAPQI begins to form protein adducts through covalent binding to cysteine residues, leading to hepatocyte injury.\(^13\) Glutathione depletion may contribute to additional injury because of oxidative stress, and hepatocyte death stimulates the innate immune system, which can also exacerbate hepatic injury.\(^16\),\(^19\) In addition to acetaminophen dose, other factors that may increase the risk of acetaminophen-related ALF after acetaminophen overdose include malnutrition, advanced age, concomitant use of CYP2E1 inducers,
concomitant use of drugs that deplete glutathione stores (e.g., sulfamethoxazole/trimethoprim), and chronic alcoholism (chronic ethanol ingestion can induce CYP2E1; in contrast, acute ethanol ingestion may offer some protection against acetaminophen-induced ALF).\textsuperscript{19}

Acetaminophen toxicity can occur as a result of both intentional and unintentional overdoses. In the United States, around 37\% of acetaminophen ALF cases are caused by intentional overdose, whereas 57\% are caused by accidental toxicity.\textsuperscript{14} Patients with unintentional overdose are more likely to have used multiple acetaminophen-containing products.\textsuperscript{20} A single acute ingestion (total consumption within 8 hours) of 7.5–10 g or greater in adults or 150 mg/kg in children younger than 6 years may result in hepatotoxicity (although these estimates may be conservative).\textsuperscript{18,19} In data collected by the ALF Study Group on acetaminophen-related ALF, the median acetaminophen dose ingested was 13.2 g/day (range 2.6–75 g/day); 83\% of the patients had ingested greater than 4 g/day, which is considered the toxic breakpoint.\textsuperscript{14}

**Idiosyncratic Drug-Induced ALF (Non-acetaminophen)**

Drug-induced liver injury (DILI) is a recognized complication of more than 1,000 drugs and supplements and has an annual incidence of 1 in 10,000–100,000.\textsuperscript{21} Drug-induced liver injury is the second most common cause of ALF in the United States, representing about 11-13\% of all ALF cases.\textsuperscript{14,22} However, less than 10\% of all DILI progresses to ALF; for example, in a study conducted by the Drug-Induced Liver Injury Network, only 6\% of all DILI cases resulted in transplantation or death.\textsuperscript{2,23} In a more recent study from the same network that evaluated 660 patients with idiosyncratic DILI, almost 10\% of all patients died or required a transplant (5\% and 4.5\%, respectively) within 6 months of DILI.\textsuperscript{24} The incidence of DILI-related ALF is about one or two cases per 1 million people per year, or 1 in 30,000–100,000 prescriptions.\textsuperscript{2,25} Drug-induced liver injury–related ALF is idiosyncratic and unpredictable and can vary in both severity and time course.\textsuperscript{2,25}
Furthermore, DILI-related ALF can be independent of the dose, route, or duration of therapy with the offending agent.\textsuperscript{25} It often follows a subacute course and can progress to ALF despite discontinuation of the precipitating drug.\textsuperscript{2} Mechanistically, it is possible that many causes of DILI-related ALF are a result of individual differences in drug metabolism (e.g., because of genetic differences) that lead to the formation of a toxic metabolite.\textsuperscript{20} Acute liver failure can be caused by either the offending agent itself or a metabolite. Damage may result from direct injury or stress, initiation of an immune response, or changes in mitochondrial function, ultimately leading to mitochondrial permeability transition and necrosis/apoptosis.\textsuperscript{26} Conventional hypersensitivity is seen in less than one-third of patients with DILI, and the liver can show either cholestatic or hepatocellular patterns of injury (the latter is associated with a worse prognosis).\textsuperscript{2} In general, the onset of DILI-associated ALF evolves more slowly than the onset observed with acetaminophen.\textsuperscript{25} Spontaneous recovery is often slow with DILI-related ALF. Overall transplant-free survival rates are around 27\%, and up to 42\% of patients require a transplant.\textsuperscript{25} Transplant-free survival may be predicted by the degree of liver dysfunction (serum bilirubin, INR, and prognostic scores [see Prognostic Indicators in ALF section]); other factors that may be related to outcome include presence of jaundice, elevated serum aminotransferases, and advanced age.\textsuperscript{2,22}

A wide variety of drugs can cause DILI-related ALF, and geographic differences exist in causative agents. In Western nations, conventional medications are commonly implicated, whereas in Asian countries, natural products and dietary supplements are commonly implicated.\textsuperscript{26} In the ALF Study Group registry, more than 60 individual agents were identified as potential causes of ALF (Box 28.1).\textsuperscript{22} The most commonly reported drug classes associated with ALF are antimicrobials (representing almost half of all cases), followed by nonsteroidal anti-inflammatory drugs, antiretroviral drugs, anticancer drugs/biologics, and dietary supplements/illicit substances.\textsuperscript{20}

**Viral Infections**
Viral infections are a relatively infrequent cause of ALF in developed nations and have gradually been declining as a cause of ALF.\(^2\) In the United States, hepatitis A virus and hepatitis B virus are the most common viral etiologies of ALF; about 7% of ALF cases are caused by hepatitis B virus and 4% of cases by hepatitis A virus.\(^{14}\) Only 1% of cases of hepatitis A virus and hepatitis B virus infections ultimately progress to ALF.\(^{20}\) Prognostic factors that may predict a poor outcome for ALF caused by hepatitis A virus or hepatitis B virus include ALT (alanine amino-transferase) less than 2,600 U/L, serum creatinine greater than 2 mg/dL, and need for intubation, vasopressors, or both.\(^{20}\) Hepatitis B–related ALF is probably initiated by an immune response and can manifest as either a primary infection or a secondary reactivation in chronic carriers (reactivation can be spontaneous or occur after immunosuppression/cancer chemotherapy).\(^{15,20}\) The liver damage related to hepatitis A virus infection is likely a result of an excessive immune response associated with a dramatic decrease in viral load.\(^{15}\) Hepatitis B–related ALF is often associated with a poor prognosis and results in death or transplantation in up to 80% of cases.\(^{3,15}\) In contrast, hepatitis A virus-related ALF is generally associated with a better prognosis than is hepatitis B virus.\(^{3,15}\)

In developing countries, hepatitis E virus is an important cause of ALF, particularly in pregnant women. Hepatitis E virus is spread through enteric transmission, and large waterborne epidemics are possible in developing regions.\(^{15,20}\) Other less common viral causes of ALF are possible, particularly during immunosuppression, including herpes simplex viruses 1 and 2, adenovirus, varicella zoster virus, and parvovirus B19.\(^{15,20}\)

**Other Causes**

In addition to the more common etiologies of ALF described earlier, there are many miscellaneous causes of ALF. These include ischemic hepatitis (i.e., “shock liver”), autoimmune hepatitis, Wilson disease, specific toxic insults (e.g., because of mushroom poisoning), the HELLP syndrome (hemolysis, elevated liver enzymes, low plate-

lets)/fatty liver of pregnancy, and the Budd-Chiari syndrome (acute hepatic vein thrombosis). Finally, in many ALF cases, there is no definite etiology; in the ALF Study Group registry, around 17% of all ALF cases were described as having an indeterminate etiology.

**PROGNOSTIC INDICATORS IN ALF**

Estimating a patient’s prognosis in ALF can be important because this may relate to the decision to proceed with OLT. However, in contrast to chronic liver diseases, the relative infrequency of ALF in conjunction with the heterogeneity of disease associated with ALF has made it difficult to develop prognostic indicators. As a result, to date, there is no single reliable prognostic scoring system used to grade the severity or prognosis of ALF, although several prognostic scoring systems have been used to help predict the need for OLT. The most commonly used prognostic models include Clichy’s criteria, the King’s College Hospital (KCH) criteria, and the Model for End-Stage Liver Disease (MELD) (Table 28.2). The Child-Pugh (Child-Turcotte-Pugh; CTP) score is not used for prognostic determinations in ALF, but it may assist in drug dosing in ALF (see text that follows). Clichy’s criteria considers plasma factor V concentrations, encephalopathy grade, and patient age; use of Clichy’s criteria is restricted in part because of the limited availability of factor V concentration measurement, the fact that the model was developed from patients with ALF with hepatitis B virus infection, and evidence that Clichy’s criteria may be less accurate than KCH criteria. The KCH criteria are more widely used than are the Clichy criteria and have separate approaches for patients with either acetaminophen or non–acetaminophen-related ALF. The KCH criteria consider both the etiology and the clinical parameters of ALF. Although the KCH criteria have a high specificity and positive predictive value (70%–100%) for identifying patients likely to have a poor prognosis, they have a low negative predictive value for poor outcome (25%–94%) (i.e., not meeting the criteria does not necessarily predict survival). The MELD score was originally developed to predict the survival of patients undergoing TIPS (transjugular intrahepatic
portosystemic shunts) and is used in some centers to identify patients who should be listed for transplantation.\textsuperscript{33,36} The MELD is a continuous score that incorporates serum creatinine, serum bilirubin, and INR (Table 28.2). Although MELD has performed better than KCH and Clichy’s criteria in some studies comparing MELD with KCH and/or Clichy’s criteria in ALF, this has not consistently been the case.\textsuperscript{33,37-39} Furthermore, it is unclear what, if any, MELD score should serve as the cutoff value indicating the need for transplantation in ALF (although scores of 30–35 are often reported as cutoffs, MELD scores can fluctuate substantially in ALF, and patients with higher MELD scores may survive without transplantation).\textsuperscript{33,39-41}

### Box 28.1. Drugs Associated with Drug-Induced ALF

**I. Antimicrobial Agents**

**A. Antituberculosis drugs 18.8%**

- Isoniazid alone 11.3%
- Isoniazid combined with two of three: rifampin, pyrazinamide, and ethambutol 4.5%
- Rifampin and pyrazinamide with or without ethambutol 2.3%
- Dapsone 0.075%

**B. Sulphur-containing drugs 9.0%**

- Trimethoprim/sulfamethoxazole alone 4.5%
- Trimethoprim/sulfamethoxazole in combination with azithromycin, statin, or antiretroviral drugs 2.3% Sulfasalazine 2.3%

**C. Other antibiotics 14.3%**

- Nitrofurantoin alone 8.3%
- Nitrofurantoin with a statin 0.75%
- Misc: amoxicillin, doxycycline, ciprofloxacin, clarithromycin, cefepime 5.3%
D. Antifungal agents 4.5%
   Terbinafine 2.3%
   Itraconazole 0.75%
   Ketoconazole alone 0.75% Ketoconazole with ezetimibe 0.75%

E. Antiretroviral drugs 3.0%
   Stavudine with didanosine 1.5%
   Lamivudine with stavudine and nelfinavir 0.75% Abacavir 0.75%

II. Central Nervous System Drugs
A. Antiepileptic drugs 8.3%
   Phenytoin 6.0%
   Carbamazepine 2.3%
   Valproic acid 1.5%

B. Psychotropic agents
   Quetiapine 0.75%
   Nefazodone 0.75%
   Fluoxetine 0.75%
   Venlafaxine 0.75%

D. Anesthetics 1.5%
   Halothane 0.75%
   Isoflurane 0.75%

III. Other Agents
A. Antimetabolites and enzyme inhibitors 8.3%
   Disulfiram 3.0%
   Propylthiouracil 3.8%
   Allopurinol 0.75%
Melphalan 0.75%

B. Nonsteroidal anti-inflammatory drugs (NSAIDs) 5.3%
   - Bromfenac 3%
   - Diclofenac 1.5%
   - Etodolac 0.75%

C. Biological agents and leukotriene inhibitors 3.0%
   - Gemtuzumab 0.75%
   - Zafirlukast 0.75%
   - Interferon beta 0.75%
   - Bacille-Calmette-Guérin (BCG) 0.75%

D. Statins and ezetimibe 4.5%
   - Cervastatin 1.5%
   - Simvastatin (± ezetimibe) 1.5%
   - Atorvastatin 1.5%

E. Other drugs 6.0%
   - Troglitazone 3.0%
   - Oxyiminoalkanoic acid derivative 0.75%
   - Methyldopa 3.0%
   - Hydralazine 0.75%

IV. Complementary and Alternative Medicine (CAM) and Illicit Substances
   - Unspecified herbal preparations 2.3%
   - Usnic acid 1.5%
   - Thermoslim (contains saw palmetto) 0.75%
     - Herbal mixture (contains blue-green algae) 0.75%
   - Ma-Huang 0.75%
   - Horny goat weed 0.75%
Clinical predictors of poor outcome in patients with ALF are likely as important as (if not more important than) prognostic scoring systems in predicting prognosis and guiding treatment decisions. These include etiology (specifically, idiosyncratic drug injury, acute hepatitis [and other non-hepatitis A virus infections], autoimmune hepatitis, mushroom poisoning, Wilson disease, and Budd-Chiari syndrome) and encephalopathy grade on admission (grade III or IV, see Table 28.3).\(^1\)

Similarly, in some studies, common intensive care prognostic models (e.g., the Acute Physiology and Chronic Health Evaluation [APACHE] II and APACHE III) have been better predictors of prognosis in ALF than have the liver-specific models mentioned previously.\(^30,42,43\) Ultimately, no single scoring system has been shown to perform reliably as an indicator of prognosis in ALF, and both methodological flaws and reporting limitations are common in existing studies.\(^44\) Therefore, the American Association for the Study of Liver Diseases (AASLD) does not recommend relying entirely on scoring systems to guide decisions regarding prognosis and need for transplantation in ALF.\(^1\)
CLINICAL PRESENTATION

Initial clinical presentation of ALF is multifactorial, varying according to the underlying etiology of the organ compromise and the time of presentation to the health care system. Early signs of ALF may include malaise, nausea, vomiting, anorexia, abdominal pain, dehydration, and fever. Initial signs of ALF are often nonspecific.\(^9\,^45\) As the metabolic and detoxification function of the liver becomes compromised in the later stages of ALF, it is anticipated that the patient will have consistent clinical features of acute loss of hepatocellular function, systemic inflammatory response, and multiorgan system failure (acute renal failure is a common manifestation of ALF).\(^1\) Clinical manifestations of ALF can be classified into three groups, based on time from the development of jaundice to the evolvement of hepatic encephalopathy. Stages may be classified as hyperacute (less than 7 days), acute (7–21 days), and subacute (3–26 weeks) (Table 28.1).\(^9\)

MANAGEMENT OF ALF

General Considerations

The foundation for the management and treatment of ALF is largely supportive care with an emphasis on prevention or progression of secondary complications. Unfortunately, no single therapy is available to improve, reverse, or prevent further evolution of ALF from all etiologies. Hospitalization with transfer to the intensive care unit is often an appropriate escalation in care for those admitted with significant hepatocellular insufficiency because rapid deterioration in neurologic status may occur, prompting the need for rapid interventions by the medical team.\(^46\) If treatment exists for the specific etiology of ALF, initiation of therapy should be prompt, followed by close monitoring of fluid status, hemodynamics, and metabolic abnormalities and surveillance of infection—considerations appropriate for all presentations of ALF. Laboratory monitoring for all patients should include evaluation of prothrombin time/INR, complete blood cell counts,
electrolytes, lactate, creatinine, blood urea nitrogen, ammonia, acetaminophen concentration, toxicology screen, viral hepatitis serologies, and autoimmune markers. Serum aminotransferases and total bilirubin should also be included in the monitoring of these patients; however, there is poor correlation between changes in these liver-specific laboratory values and prognosis.

Pharmacologic Treatment

Acetylcysteine

Acetylcysteine, a hepatoprotective agent, is an established antidote for acetaminophen toxicity. Acetylcysteine exerts its effects by restoring hepatic glutathione stores through the replenishment of cysteine, enhancing the sulfation pathway of acetaminophen elimination, and may result in a reduction reaction of NAPQI back to acetaminophen. Acetylcysteine is available in both intravenous and oral preparations. The oral formulation of acetylcysteine undergoes extensive first-pass metabolism by the liver, resulting in a low yield of available drug. However, acetylcysteine undergoes deacetylation in the liver to produce cysteine, which may be of benefit given that cysteine is the rate-limiting factor in glutathione production. In contrast, intravenous administration of acetylcysteine bypasses first-pass metabolism and may subsequently result in lower glutathione concentrations than oral administration. The U.S. Food and Drug Administration (FDA)-approved recommendations for oral administration of acetylcysteine require a minimum treatment duration of 72 hours. The oral dosage regimen consists of a 140-mg/kg loading dose followed by maintenance dosing of 70 mg/kg every 4 hours for 18 doses or a total cumulative dose of 1330 mg/kg. Intravenous administration of acetylcysteine is provided over a minimum of 21 hours in three doses. Administration should include an initial loading dose of 150 mg/kg (maximum of 15 g) infused over 60 minutes, followed by a dose of 50 mg/kg (maximum of 5 g) infused over 4 hours, and ending with a third dose of 100 mg/kg (maximum of 10 g) infused over 16 hours.
The most commonly reported adverse effects of the intravenous form include the dose-dependent anaphylactoid reactions of tachycardia, hypotension, edema, rash, pruritus, nausea, vomiting, bronchospasms, and angioedema. The incidence of adverse events noted with the intravenous form is reduced substantially when acetylcysteine is administered orally.\textsuperscript{47} Although a systematic review did not provide conclusive evidence to support one route of acetylcysteine administration over another, the intravenous route of administration remains the preferred route for most acute ingestions.\textsuperscript{48}

• According to AASLD, also consider unfavorable etiology such as Wilson disease, idiosyncratic drug reaction, seronegative hepatitis¹

**Model for End-Stage Liver Disease (MELD)**³¹

- MELD = 3.78 × ln[serum bilirubin (mg/dL)] + 11.2 × ln[INR] + 9.57 × ln[serum creatinine (mg/dL)] + 6.43 × etiology (0: cholestatic or alcoholic, 1: otherwise)
- If patients have had dialysis twice per week in the previous 7 days, the serum creatinine value is set at 4.0 mg/dL
- Laboratory values < 1.0 are set as 1.0 (to avoid negative values)

- Unclear what cutoff value should be used to determine candidates for transplantation, not developed or validated for ALF

AASLD = American Association for the Study of Liver Diseases; ALF = acute liver failure; PTT = partial thromboplastin time.

Greatest success with administration of acetylcysteine for the prevention of hepatic toxicity and subsequent ALF is seen when administration occurs within 8 hours of toxic acetaminophen ingestion. As the delay in acetylcysteine therapy extends beyond 8 hours of acetaminophen poisoning, antidotal effects decrease, and risk of ALF increases. Despite decreased efficacy when acetylcysteine is administered further from the time of an acute toxic acetaminophen ingestion, initiation of acetylcysteine regardless of post-ingestion time
is typically favored because the potential benefit of administration outweighs the risk associated with its use. Hepatotoxicity risk after acetaminophen ingestion can be assessed by plotting the serum acetaminophen concentration and the corresponding hours post-ingestion on the Rumack-Matthew nomogram (Figure 28.1). To use this tool effectively, a random serum acetaminophen concentration must be obtained between 4 hours and 24 hours of ingestion. If the time of ingestion is unknown, the Rumack-Matthew nomogram cannot be used to assess the need for treatment and the potential risk of hepatotoxicity. Therefore, an elevated serum acetaminophen concentration is typically treated regardless of post-ingestion time because the benefits of acetylcysteine vastly outweigh the risk of administration. If a serum acetaminophen concentration is obtained, the hour of ingestion is known, and the post-ingestion time fits within the targeted time interval of 4–24 hours, the concentration can be plotted on the Rumack-Matthew nomogram to assess the need for initiating acetylcysteine. The treatment line, also known as the parallel line at 150 mcg/mL 4 hours post-ingestion on the nomogram, is the most commonly used guideline for acetylcysteine initiation after toxic ingestion of acetaminophen.

Administering acetylcysteine may also provide beneficial effects after hepatic injury in non-acetaminophen-induced ALF and alcoholic hepatitis. Efficacy of acetylcysteine administration in these clinical presentations is unrelated to detoxification. Presumed beneficial mechanisms of action in these clinical scenarios include scavenging of free radicals and replenishment of glutathione stores during oxidative stress, production of nitric oxide resulting in vasodilation and hepatic
perfusion, and anti-inflammatory properties through inhibition of proinflammatory factors. In the treatment of non–acetaminophen-induced ALF, administration of oral and intravenous acetylcysteine has shown increased transplant-free survival rates and decreased length of hospitalization. For the treatment of severe alcoholic hepatitis, acetylcysteine has also shown theoretical benefits secondary to the antioxidant and anti-inflammatory effects. Again, despite varying data regarding benefit for acetylcysteine in non–acetaminophen-induced ALF and alcoholic hepatitis, initiation of acetylcysteine is typically favored because the potential benefits of administration outweigh the risks associated with its use.

Management of Secondary Complications

Hepatic Encephalopathy

The hallmark complication of ALF, hepatic encephalopathy, is related to cerebral edema and intracranial hemorrhage (ICH). As the severity of hepatic encephalopathy increases, denoted by grade (see Table 28.3), the rate of cerebral edema and ICH increases. These detrimental effects of hepatic encephalopathy are a result of hyperammonemia. Pharmacologic management of hepatic encephalopathy and less invasive medical interventions (excluding electroencephalogram, mechanical ventilation, and artificial liver systems) can typically bridge patients with grade I and II hepatic encephalopathy. As patients progress to grade III and IV hepatic encephalopathy, intubation and subsequent mechanical ventilation become mandatory to provide supportive care until the symptoms improve or resolve. Pharmacologic therapies for the management of hepatic encephalopathy mitigate their action through lowering of ammonia, with a focus on the ammonia-producing bacteria of the colon. Disaccharides are considered the first-line pharmacologic agents of choice for lowering the production and absorption of ammonia, with lactulose being the most commonly used agent. Lactulose is metabolized by the gut flora into acetic and lactic acids, producing an acidic, non-survival
environment for the bacteria. In addition, the metabolism of lactulose inhibits the diffusion of ammonia into the systemic circulation and the subsequent conversion of ammonia to ammonium. Lactulose for hepatic encephalopathy can be administered by enteral access or per rectum and is typically titrated to 2–4 semisoft stools per day. Despite mechanistic belief of efficacy, conflicting data exist regarding substantial benefit in the treatment of hepatic encephalopathy compared with placebo. Currently, there is insufficient evidence to dispute the initiation of lactulose therapy; therefore, lactulose (or other laxative agents discussed in the following text) should be administered to all patients with hepatic encephalopathy.49

Despite the long-standing use of disaccharide therapy in hepatic encephalopathy, recent evidence is challenging its role as the first-line treatment option for hepatic encephalopathy. Polyethylene glycol, an osmotic laxative with gut catharsis activity, was hypothesized to resolve hepatic encephalopathy more effectively than lactulose in the Hepatic Encephalopathy: Lactulose vs Polyethylene Glycol 3350-Electrolyte Solution (HELP) study. Efficacy was evaluated by an improvement in one or more grades of hepatic encephalopathy at 24 hours after the administration of pharmacologic intervention. Therapies evaluated include lactulose 20–30 g orally or 300 g per rectum for a minimum of three doses in 24 hours compared with polyethylene glycol 4 L orally over 4 hours. Patient demographics were similar in each treatment group, including severity of liver failure. A statistically significant improvement in one or more grades of hepatic encephalopathy was noted in the polyethylene glycol treatment arm compared with the lactulose therapy treatment arm (91% vs. 52%; p<0.01). Use of polyethylene glycol was also shown to have a shorter time to hepatic encephalopathy resolution (1 day vs. 2 days; p = 0.01). However, patients who received polyethylene glycol had a nonstatistically significant shorter duration of hospital stay; therefore, polyethylene glycol may provide more rapid improvement in hepatic encephalopathy, but the long-term benefits of this agent, in place of conventional disaccharide therapy, remain unknown. In addition, the dosing scheme used in the HELP study may be unrealistic for long-term adherence.50
Oral antimicrobials have been evaluated as an alternative treatment option for the management of hepatic encephalopathy. Similar to the goal with disaccharides, the goal with antimicrobial therapy in hepatic encephalopathy is the inhibition of ammonia production by intestinal bacteria. Agents evaluated for possible efficacy include neomycin, metronidazole, vancomycin, and, most recently, rifaximin. Use of neomycin, metronidazole, and vancomycin has decreased substantially in the treatment of hepatic encephalopathy because of toxicities and emerging resistance. Neomycin administration has been associated with increased risk of nephrotoxicity and ototoxicity, and neurotoxicity has been associated with metronidazole. Because of the emergence of vancomycin-resistant enterococci, use of vancomycin for hepatic encephalopathy is limited to cases of resistance. Rifaximin has optimal pharmacokinetic and pharmacodynamic properties because it has minimal systemic absorption and high intraluminal and fecal drug concentration with a broad spectrum of activity against gram-positive, gram-negative, anaerobic, and aerobic organisms. Compared with therapy for hepatic encephalopathy with disaccharides, rifaximin has shown varying results. A prospective, double-blind, randomized controlled trial of 120 patients compared rifaximin plus lactulose with lactulose alone in the treatment of overt hepatic encephalopathy. No significant difference was noted between treatment groups with respect to severity of liver failure, etiology, grade of hepatic encephalopathy, or previous episodes of hepatic encephalopathy. There was a statistically significant rate of reversal of hepatic encephalopathy within 10 days of therapy in the group receiving rifaximin plus lactulose compared with the group receiving lactulose alone. In addition, patients in the combination therapy group had a statistically significant shorter duration of hospital admission and decreased rate of mortality. Therefore, it can be concluded that rifaximin is at least as efficacious as, if not superior to, lactulose, but use may be restricted by severity of illness because of the higher cost of this agent than of laxative therapy.

Cerebral Edema/Intracranial Hypertension
Cerebral edema and ICH are the most serious complications of ALF and are the main cause of morbidity and mortality in ALF. However, the underlying mechanism of cerebral edema and ICH is not well known. It is hypothesized that this adverse consequence of ALF is related to osmotic disturbances because of hyperammonemia and loss of cerebral blood flow autoregulation. Risk factors for developing cerebral edema and ICH include grade III or IV encephalopathy (Table 28.3), serum ammonia concentrations greater than 200 micromoles/L, and need for vasopressor or renal replacement therapies.

Universal interventions should be applied to patients with high-grade hepatic encephalopathy. Recommendations include elevation of the head of the bed by 30 degrees, endotracheal intubation, management of hypertension, and minimization of painful stimulation or agitation. Placement of ICP monitoring may be considered in these patients if patients are at a center with expertise in this area. Monitoring of ICP allows for evaluation of cerebral hypoperfusion through calculation of cerebral perfusion pressure (CPP; mean arterial pressure minus ICP), with the goal of maintaining a CPP of at least 50–60 mm Hg. Episodes of cerebral hypoperfusion, denoted by a CPP less than 50–60 mm Hg, place the patient at an increased risk for developing cerebral ischemia and secondary long-term cognitive detriments. Even though ICP monitoring can provide the clinician with a more clear understanding of the patient’s cerebral edema and ICH status, ICP devices have not shown improvements in patient survival rates compared with patient survival rates without this invasive monitoring, and the devices are associated with greater risk (infection and hemorrhage) to the patient.

Prevention strategies, as well as interventions in the management of ICP, mimic those identified for the treatment of elevated ICP in the trauma population. If an ICP monitor is present, the ICP should be maintained at 20–25 mm Hg with mean arterial pressure greater than 70 mm Hg to allow for achievement of a CPP greater than 50 mm Hg. Achievement and maintenance of a target CPP often require a balancing act of increasing the mean arterial pressure to the safest possible degree while minimizing the ICP. Vasopressor therapy may be necessary to assist in the elevation of the mean arterial pressure, with
norepinephrine typically being the most appropriate first-line agent. To achieve goal ICP, osmotic therapy may be considered. Administration of intravenous mannitol has been shown to decrease elevated ICP in patients with ALF; however, use of mannitol in severe ICH has shown minimal to no benefit. Despite weaker evidence for use in more severe cases, mannitol remains the first-line therapy for ICH in ALF, according to the AASLD ALF management guidelines.\textsuperscript{1} Mannitol should be administered as an intravenous bolus of 0.5–1 g/kg. Additional doses may be administered if the patient’s serum osmolality remains less than 320 mOsm/L.\textsuperscript{1,9} When additional doses of mannitol are contraindicated because of serum osmolality, administration of hypertonic sodium chloride may be considered. Hypertonic sodium chloride has shown similar efficacy to mannitol in the management of ICH in ALF.\textsuperscript{9} The AASLD guidelines recommend prophylactic administration of hypertonic sodium chloride in patients at highest risk of developing cerebral edema—outlined as those with hyperammonemia, grade III or IV hepatic encephalopathy, acute renal failure, or administration of vasopressor therapy.\textsuperscript{1} Hypertonic sodium chloride should be administered by intravenous bolus administration at a frequency of every 2–3 hours. While administering hypertonic sodium chloride, it is important to monitor serum sodium often with the goal of achieving a concentration of 145–155 mmol/L.\textsuperscript{46} If ICP remains elevated despite an adequate challenge of mannitol, hyper-tonic saline, or both, barbiturate agents may be considered.\textsuperscript{1} A barbiturate coma induced by pentobarbital administration of 3–5 mg/kg intravenous load followed by 1–3 mg/kg/hour has been correlated with improvement in ICP in patients who are refractory to conventional therapy of mannitol or hypertonic sodium chloride.\textsuperscript{46} Despite a benefit in decreasing ICP, barbiturate administration is often limited by hypotension, which subsequently results in a decreased CPP. The final pharmacologic agents that may be considered are corticosteroids. Although corticosteroids have shown benefit in ICH, their use is limited to elevations in ICH secondary to brain tumors and some infectious pathologies. Therefore, there is no clinical benefit to administering corticosteroids in patients with ALF despite the presence of ICH.\textsuperscript{1}
Interventions outside pharmacologic therapies have been evaluated for the management of ICH, including induction of hyperventilation and hypothermia. Despite perceived mechanistic benefit, both interventions have failed to provide substantial improvement; therefore, the AASLD guidelines do not recommend the induction of hyperventilation and hypothermia in the management of ICH in ALF. Hyperventilation, denoted by a partial pressure of carbon dioxide of 25–30 mm Hg, provides restoration in cerebrovascular autoregulation and subsequent improvement in ICP. Despite this benefit, the duration of effects provided by hypoventilation is short-lived. Hypothermia has been evaluated as a method to control and prevent ICH as well as prevent cerebral edema.\(^1\) The mechanisms through which hypothermia has been proposed to prevent cerebral edema include hyperemia, alteration in metabolism of ammonia and glucose, and reduction in cerebral metabolism and blood flow. However, most data evaluating the benefit of hypothermia are derived from animal models, with only limited experience in human subjects.\(^1,54\) To date, data evaluations are lacking to recommend hypothermia as a treatment modality for the management of ICH in ALF.

Seizure prophylaxis has been evaluated in the management of cerebral edema and ICH because it is known that seizure activity can increase the ICP as well as result in cerebral hypoxia and subsequent edema. Despite several trials evaluating the role of seizure prophylaxis in ALF, clinical studies are inconclusive for a benefit in this population; seizure prophylaxis is therefore not recommended by the AASLD management guidelines.\(^1\) Although prophylactic administration of antiepileptics is not recommended, monitoring of epileptiform discharge should be conducted by electroencephalogram for the following indications: grade III or IV hepatic encephalopathy, sudden change in neurologic status, myoclonus, or during titration of barbiturate therapy for management of cerebral edema.\(^46\) If seizure activity does present, prompt control of the seizure and initiation of maintenance therapy should be considered in accordance to standard epilepsy treatment with phenytoin or an equivalent antiepileptic.\(^1\)
**Infection**

Despite impairment of host-defense mechanisms in patients with ALF, there is lack of evidence to suggest empiric initiation of antibacterial or antifungal therapy.\(^1,45\) However, surveillance monitoring for signs and symptoms of an infectious source should be implemented because etiologies of the ALF may mask symptoms of systemic infection—particularly fever in the presence of acetaminophen-induced ALF. Prompt collection of blood cultures and early evaluation of chest radiographs should occur at the earliest signs of infection or neurologic deterioration. The most common site of infection is the lungs, followed by the urinary tract and the bloodstream. Infectious organisms most commonly isolated from this population include gram-negative enteric bacilli, gram-positive cocci, and *Candida* spp.\(^9\) Empiric antimicrobial administration should be considered in patients when surveillance cultures denote a significant infecting organism, worsening hepatic encephalopathy, hypotension nonresponsive to traditional interventions, and presence of systemic inflammatory response syndrome criteria. Initial therapy should provide a broad spectrum of antimicrobial coverage, covering *Staphylococcus*, *Streptococcus*, *Escherichia coli*, and *Enterobacter* spp., and should consider local rates of susceptibilities. In patients who are OLT candidates, there may be a lower threshold to initiate empiric antimicrobial therapy because a recent or active infection may reduce the success of transplantation or delay the OLT procedure.\(^9,46\)

**Coagulopathy**

Coagulopathy commonly presents with the development of ALF and is typically denoted by the laboratory findings of thrombocytopenia, prolonged prothrombin time/INR, or both. This disorder arises as a result of inadequate synthesis of fibrinolytic proteins, anticoagulant proteins, and precoagulation factors as well as enhanced consumption of clotting factors and dysfunction in platelet activity.\(^9,45,46\) This disruption in the coagulation pathway results in a mismatch of hypercoagulable and coagulopathic states, but often, these differing
hematologic states balance each other. Therefore, the frequency of spontaneous, clinically relevant bleeding episodes is low, with a reported incidence of less than 10%. If a bleeding episode occurs, it commonly presents in the mucosa of the stomach, lungs, or gastrointestinal (GI) tract. Therefore, patients admitted to the intensive care unit with the presence of ALF should receive either histamine-2 receptor blocking agents or proton pump inhibitors, both considered first-line agents, for stress ulcer prophylaxis of the GI tract. Sucralfate may be used as a second-line option for patients with existing contraindications to first-line therapy.

Patients with ALF may have a vitamin K deficiency. Because of this deficiency and the coagulation abnormalities, it is recommended to empirically administer vitamin K to these patients. The AASLD guidelines recommend administering vitamin K 5–10 mg subcutaneously, typically for 3 days. However, subcutaneous vitamin K is known to have erratic absorption in patients with ALF, so use of the intravenous or oral formulations is usually preferred. Beyond administering vitamin K, complete correction or reversal of coagulopathies and associated abnormal laboratory values is not recommended for all patients presenting with ALF. Administration of fresh frozen plasma (FFP), platelets, recombinant factor VIIa, or cryoprecipitate to reverse coagulopathy should be reserved for patients with an active bleed or for patients requiring invasive interventions, such as the placement of an ICP monitor for management of cerebral edema and ICH. When reversal is required, FFP is typically the initial agent used to correct the coagulation abnormality. Administration of recombinant factor VIIa should be reserved for patients whose reversal with FFP has failed. Timing of administration of recombinant factor VIIa in relation to planned intervention is crucial for efficacy because this agent has a short terminal half-life. It is recommended interventions be done 20–30 minutes after administration. Cryoprecipitate should be reserved for the patient’s demonstration of hypofibrinogenemia, denoted by a serum fibrin concentration less than 100 mg/dL. Furthermore, transfusion of platelets should be reserved for cessation of active bleeding in patients
with a platelet count of less than 10,000/ mm$^3$ to 50,000/mm$^3$.\textsuperscript{9,46}

**General Supportive Care**

The management of metabolic derangements, nutrition, and renal failure in the ALF population mimics standard care for other critically ill patients. Information regarding these topics can be found in Chapter 3, “Electrolytes,” Chapter 4, “Nutrition Support,” and Chapter 26, “Acute Kidney Injury—Prevention and Management.”

**Nonpharmacologic Management**

**Extracorporeal Liver Support**

Extracorporeal liver support systems, or liver assist devices, have been developed to mimic the function of the liver in patients with ALF, acute on chronic liver failure, and end-stage liver disease.\textsuperscript{9,55} Using a concept similar to the function of external devices used in renal replacement therapy, extracorporeal liver support systems may serve as a bridge therapy until recovery or transplantation. Many systems have been developed and can be classified into nonbiological and biological systems. Activity of the non-biological systems is provided through the elimination of albumin-bound water-insoluble molecules (including, but not limited to, bilirubin, bile acids, fatty acids) using high-flux membrane extracorporeal liver support systems. Biological extracorporeal liver support systems differ because of the use of living hepatocytes, which provide detoxification as well as synthetic and metabolic activity.\textsuperscript{55} Despite the potential efficacy of extracorporeal liver support systems in ALF, randomized controlled trials have failed to show long-term benefits. An additional limitation to the use of these systems is their lack of availability in many health care institutions. Further development and research of these devices is needed to warrant the routine implementation of these devices in the management of ALF.\textsuperscript{1,55}

**Liver Transplantation**
The management of ALF with irreversible injury is limited to OLT because this intervention serves as the only definitive treatment option.\textsuperscript{9} Acute liver failure accounts for about 5%–6% of OLT performed in the United States.\textsuperscript{56,57} The timing of referral for OLT provides some complexity in the management of ALF; referral should be made in enough time to allow for assessment of candidacy but should not be delayed to the extent that the patient’s level of critical illness impedes the patient’s surviving the procedure. Acute liver failure is one of the few conditions that allows for status 1A (urgent) placement on the United Network for Organ Sharing.\textsuperscript{1} Calculation of the patient’s MELD score, as well as evaluation of relative and absolute contraindications to transplantation, must be completed in the consideration of listing for transplantation. Relative contraindications include age older than 65, severe malnutrition, other organ failure, previous abdominal surgery, poor functional status, and poor medical compliance. Severe cardiopulmonary disease, irreversible cerebral injury, sepsis or active infection, HIV, extrahepatic malignancy, vascular anomaly or thrombosis, active alcohol or illicit drug use, and psychosocial issues are commonly considered contraindications to OLT.\textsuperscript{56} Survival rate 1 year after OLT in patients with ALF (75\%) is less than in those who receive a transplant for chronic liver failure (87\%).\textsuperscript{1,56} However, patients who receive OLT for ALF tend to have better long-term survival (survival beyond the first year). Therefore, urgent OLT should be considered in those with prognostic indicators indicating low probability of survival.\textsuperscript{1}

**DRUG DOSING IN ALF**

The liver plays an integral role in the pharmacokinetics of numerous drugs, and impaired hepatic function can affect drug metabolism, biliary excretion, and plasma protein binding.\textsuperscript{58} Unfortunately, most data regarding the impact of hepatic dysfunction come from studies of chronic liver diseases, and information is limited on the impact of ALF on drug pharmacokinetics and drug dosing modifications. Furthermore, existing studies often group patients with different etiologies and
severity of liver disease (that may be associated with a broad range of pharmacokinetic changes).\textsuperscript{59} Despite this lack of information, the rapid loss of liver function and massive necrosis/apoptosis associated with ALF can be expected to have clinically important effects on drug pharmacokinetics that may warrant changes in drug dosing.\textsuperscript{60} Patients with ALF may also have acute renal failure, which can reduce the clearance of renally eliminated drugs. Ultimately, ALF can significantly affect several key pharmacokinetic processes, including absorption, distribution, metabolism, and elimination.\textsuperscript{60} In the section that follows, we review the basic principles of hepatic drug clearance and discuss potential mechanisms of altered drug pharmacokinetics that may warrant changes in drug therapy.

**Principles of Hepatic Drug Clearance**

Hepatic drug clearance is a function of the hepatic blood flow (Q$_H$) and the hepatic extraction ratio (E$_H$) of a given drug.\textsuperscript{58} Intrinsic hepatic drug clearance (CL$_\text{int}$) represents the metabolism of unbound drug (i.e., it is independent of Q$_H$ and extent of protein binding) by the liver.\textsuperscript{61} The E$_H$ represents the efficiency with which the liver clears a drug from the circulation, and using E$_H$, drugs can be classified as having high (E$_H$ greater than 0.6), intermediate (E$_H$ 0.3–0.6), or low (E$_H$ less than 0.3) E$_H$ values (Table 28.4).\textsuperscript{58,61} The primary determinants of drug metabolism are Q$_H$, the extent of plasma protein binding, and CL$_\text{int}$. The metabolism of drugs with high E$_H$ is limited by liver blood flow and is relatively insensitive to changes in plasma protein binding and the activity of drug-metabolizing enzymes. In contrast, the metabolism of drugs with low E$_H$ is more dependent on alterations in hepatic enzyme function (i.e., CL$_\text{int}$) and plasma protein binding, and less dependent on Q$_H$. Drugs with intermediate E$_H$ values can be affected to some extent by changes in Q$_H$, plasma protein binding, and CL$_\text{int}$. In addition to affecting hepatic clearance, E$_H$ affects the bioavailability of enterally administered drug; drugs with high E$_H$ tend to undergo substantial first-
pass metabolism, whereas drugs with low $E_H$ are generally not subject to substantial first-pass metabolism by the liver.\textsuperscript{62}

**Potential Mechanisms of Altered Drug Disposition in ALF**

Many pathological changes during ALF can contribute to altered drug disposition, making prediction of pharmacokinetics difficult. Potential physiologic changes leading to pharmacokinetic changes include (but are not limited to) a reduction in hepatocyte cell mass, alterations in hepatic perfusion (including portal venous perfusion and arterial perfusion), alterations in hepatic enzyme and hepatic transporter function, alterations in hepatic protein synthesis, and alterations in renal function associated with ALF.\textsuperscript{63} A discussion of how various pharmacokinetic processes may be affected by ALF is presented in the following section.

**Alterations in Drug Absorption**

Acute liver failure can alter the oral bioavailability of enterally administered drugs by several mechanisms. Alterations in intestinal permeability caused by the inflammation associated with ALF may affect drug absorption from the intestine, although these changes are not well characterized, and may be affected by several mechanisms (i.e., alterations in passive permeability, alterations in mucosal transporter function, etc.). Similarly, enteral absorption can be influenced by alterations in gastric motility that may be present in ALF.\textsuperscript{60} More importantly, ALF may be associated with changes in hepatic first-pass metabolism. Under normal conditions, after oral administration, high $E_H$ drugs are extensively (greater than 60%) removed from the liver by first-pass metabolism (i.e., bioavailability less than 40%), whereas low $E_H$ drugs are not significantly removed by first-pass metabolism (first-pass removal of 30% or less).\textsuperscript{61} A reduction in the drug-metabolizing capacity of the liver during ALF is expected to result in an increase in the enteral bioavailability of high $E_H$
Similarly, alterations in blood flow from the intestine to the liver may also contribute to increased enteral bioavailability, although these changes are not as well characterized in ALF as in chronic hepatic diseases. Therefore, intravenous administration of high $E_H$ drugs may be preferred to enteral administration. If enteral administration of high $E_H$ drugs is used, initial doses should be lowered (see text that follows). Examples of high $E_H$ drugs are shown in Table 28.4. The enteral bioavailability of low $E_H$ drugs is less likely to be affected by ALF.

Alterations in Drug Distribution

Alterations in plasma protein concentrations in ALF can affect the volume of distribution of drugs that are highly protein bound (i.e., drugs with 90% or greater protein binding).\textsuperscript{62} Potential mechanisms for decreased plasma protein binding include impaired hepatic protein synthesis, accumulation of exogenous compounds that can inhibit protein binding (e.g., bilirubin), and potential qualitative changes in albumin.\textsuperscript{58,60} Reductions in plasma albumin in ALF can lead to higher concentrations of free drug for agents that are highly bound to albumin.\textsuperscript{58} This may be clinically important because the unbound drug is generally responsible for generating a pharmacologic effect.\textsuperscript{61} Furthermore, changes in the concentration of unbound drug resulting in changes in volume of distribution may lead to alterations in clearance.\textsuperscript{62} Simultaneous increases in unbound fraction and decreases in metabolism (see text that follows) of highly bound drugs cleared by the liver can result in toxicity.\textsuperscript{62} Because the time course of ALF is variable and the half-life of albumin is relatively long (i.e., about 21 days), reductions in plasma albumin are not as predictable in ALF as in chronic liver diseases. Volume of distribution may also be influenced by third spacing (because of ascites, edema, or both); this may be particularly important for hydrophilic drugs (e.g., aminoglycosides).\textsuperscript{60}

**Alterations in Drug Metabolism and Clearance**

In general, hepatic drug metabolism is likely impaired in patients with ALF, although most available data come from chronic liver diseases. Hepatic metabolism may be impaired because of several mechanisms. Hepatic transporters mediate the transport of some drugs in or out of hepatocytes and into the bile canaliculus. Transporter expression and activity may be altered in acute and chronic liver diseases; however, a detailed discussion of transporter alterations is beyond the scope of this chapter.\(^60\) Alterations in hepatic enzymatic capacity (including alterations in hepatic enzyme expression and loss of hepatocytes) can substantially affect hepatic drug metabolism.\(^60\) The effect of ALF on drug metabolism may partly depend on whether the drug is a high, intermediate, or low extraction drug.\(^60\) As indicated earlier, \(E_H\) describes the efficiency of drug removal by the liver and is dependent
on $Q_H$, $CL_{int}$, and plasma protein binding. Intrinsic drug clearance is an indication of the liver’s ability to clear unbound drug from the blood and depends on hepatic metabolic enzyme activity and the function of hepatic transporters. Therefore, ALF may result in a reduction in $E_H$ because of a reduction in the expression and activity of drug-metabolizing enzymes and may further affect metabolism as a result of changes in $Q_H$. The hepatic drug clearance of low $E_H$ drugs tends to be sensitive to changes in enzyme activity and protein binding. High $E_H$ drugs are more sensitive to alterations in $Q_H$. Although specific data regarding hepatic enzyme activity in ALF are lacking, data in chronic liver diseases such as cirrhosis can offer insight into probable alterations. Cytochrome P450 enzymes are likely more affected in cirrhosis than are phase II metabolizing enzymes. The extent to which liver disease affects drug metabolism depends on several factors, including the metabolic pathway involved, extent of injury, and time course of injury. Results of studies in cirrhosis have been variable; however, in general, the activity and expression of CYP3A, CYP1A2, and CYP2C19 appear to be most susceptible to the effects of chronic liver disease, whereas CYP2D6 and CYP2C9 may be more preserved. In a study evaluating CYP3A activity in cirrhosis, CYP3A activity was correlated with CTP and MELD scores. In this study of patients with severe cirrhosis (CTP class C or MELD of 15 or higher), the unbound clearance of midazolam (a CYP3A substrate) was 14% of the corresponding midazolam clearance in control subjects. Although caution should be used in extrapolating these results to ALF, it is likely that ALF is associated with a reduction in CYP function and expression, given the extensive hepatocyte necrosis and apoptosis that is characteristic of ALF. In one of the few pharmacokinetic studies conducted in ALF, the plasma half-life of antipyrine was significantly prolonged in patients after acetaminophen overdose (antipyrine is a substrate for several CYP enzymes, including CYP1A2, CYP2C9, and CYP3A4). Similarly, in a study that included eight subjects with acute hepatitis (out of 18 total subjects with liver disease), antipyrine clearance was decreased compared with controls, and this was most pronounced in patients with encephalopathy. Of note, an in vivo test
of CYP1A2 as a measure of liver function (LiMAx test) showed decreased CYP1A2 function in patients with ALF, with lower function in patients with ALF without spontaneous recovery than in patients with ALF with spontaneous recovery.\textsuperscript{69} For low $E_H$ drugs, changes in protein binding can also affect metabolism (see earlier text). Specifically, low $E_H$ drugs with high protein binding may be sensitive to alterations in protein binding that may be present in ALF.\textsuperscript{60}

\textsuperscript{a}This is an abbreviated list and does not contain all drugs with dosing guidelines based on Child-Pugh (CTP) score.

\textsuperscript{b}CTP score was not designed for use in ALF and has not been validated in ALF. Proposed approaches for patients with ALF include calculating an individual patient’s CTP score or assuming that the patient has severe disease (CTP class C, score 10–15).

Phase II enzymes may also be affected by ALF, although they are
generally thought to be less affected than phase I enzymes in chronic liver diseases.\textsuperscript{60} For example, the metabolism of benzodiazepines eliminated by phase II reactions (e.g., oxazepam, temazepam, lorazepam) may be less likely to have reduced clearance than benzodiazepines metabolized by phase I reactions (e.g., midazolam, diazepam).\textsuperscript{70} In general, sulfonation reactions are more affected than glucuronidation.\textsuperscript{60} Acute liver failure is often associated with renal dysfunction, which affects the renal clearance of drugs, and should be accounted for when selecting a dosing regimen.

**Guidelines for Drug Dosing in ALF**

The relative paucity of data regarding pharmacokinetic changes in ALF, in combination with the variability in the presentation of ALF, limits the ability to develop specific dosing guidelines. However, several generalizations may be made. First, when available, serum drug concentrations should be monitored to assist in drug dosing in ALF, and when possible, monitoring of free drug concentrations may be preferred (to monitoring of total concentrations).\textsuperscript{62} Unfortunately, serum concentration monitoring is available for only a minority of drugs used clinically.

For some drugs, dosing recommendations based on the CTP score may be available; however, these recommendations are generally based on chronic liver diseases, not ALF.\textsuperscript{62} The CTP classification assigns points according to the presence of ascites and encephalopathy, as well as serum bilirubin, albumin, and prothrombin time (Table 28.5).\textsuperscript{32} The patient is classified as having mild, moderate, or severe disease. Although the CTP score was not developed for the intent of drug dosing, the FDA has included its use in a guidance statement for pharmacokinetic studies in hepatic impairment, and dosing guidelines based on the CTP score are included in the labeling of some drugs (see Table 28.6 for examples). In the absence of dosing recommendations specific to ALF, guidelines based on the CTP score may be used as an initial guide to dose drugs in ALF (i.e., either using patient characteristics to calculate a CTP score or assuming the
patient has severe disease). For drugs with no dosing guidelines based on CTP scores, doses may be adjusted on the basis of a drug’s $E_H$ and protein binding (see Table 28.7).\textsuperscript{70,71}

| Enteral bioavailability   | • May be increased, particularly with high $E_H$ drugs | • Consider parenteral formulation if available  
  - A conservative approach is to assume 100% bioavailability of high $E_H$ drugs, and dose using the formula: adjusted initial dose = (normal dose $\times$ bioavailability in normal liver function)/100\textsuperscript{a}  
  • Consider lower dose |
| Volume of distribution    | • Increases in free concentrations of drugs highly bound to albumin  
  • Potential increases in volume of distribution of hydrophilic drugs in the setting of ascites/edema | • Consider monitoring free drug concentrations, if available  
  • Account for changes in protein binding when interpreting total drug concentrations  
  • Consider higher loading doses for hydrophilic drugs (e.g., aminoglycosides) in the setting of ascites |
| Clearance                 | • Impaired hepatic drug metabolism by CYP enzymes  
  • High $E_H$ drugs are more sensitive to alterations in hepatic blood flow (e.g., during shock)  
  • Low $E_H$ drugs are more sensitive to alterations in CYP | • Consider therapeutic drug monitoring, if available  
  • For drugs with guidelines based on CTP score, consider using clinical characteristics to estimate a CTP score and follow guidelines for severe disease\textsuperscript{b}  
  • In the absence of dosing guidelines based on CTP score, the following guidelines may be considered: |
activity and protein binding

- For high $E_H$ drugs administered orally: initial maintenance dose = (normal dose $\times$ bioavailability in normal liver function)/100$^a$

- For high $E_H$ drugs administered intravenously: initial maintenance dose = normal dose$^a$

- For low $E_H$ drugs with low binding to albumin ($< 90\%$ binding): initial dose = normal initial dose, maintenance dose should be reduced to 50\% of normal in patients with calculated CTP class A, reduced to 25\% of normal dose in calculated CTP class B; for calculated CTP class C, avoid drugs without proven safety in this population, or initiate low dose and monitor therapy closely$^a$

- For low $E_H$ drugs with high binding to albumin ($\geq 90\%$ binding): monitor therapy closely$^a$

- For intermediate $E_H$ drugs, initial dose is the low range of normal dose; maintenance dose should be adjusted on the basis of guidelines for low $E_H$ drugs

  • Closely monitor patients for efficacy and signs of toxicity
  • Adjust doses as necessary on the basis of renal function

$^b$The CTP (Child-Pugh) score was not developed for use in acute liver failure.

$E_H$ = hepatic extraction ratio.

It is likely that drugs with a high $E_H$ will have an increased enteral
bioavailability in ALF; in these cases, administering lower doses (and gradually titrating doses on the basis of response and toxicity) or using parenteral administration may be warranted. If enteral administration of a drug with high $E_H$ is required, a conservative approach is to assume 100% bioavailability of these agents and to dose on the basis of the following formula: adjusted initial dose = (normal dose × bioavailability in normal liver function)/100.\(^7\)

Acute liver failure is often associated with acute renal failure, which may warrant a dose adjustment of drugs that are cleared through the kidneys. Furthermore, management of ALF and acute renal failure may require the use of extracorporeal support systems (e.g., molecular adsorbent recirculating systems, renal replacement therapy). Information regarding drug dosing in renal failure and during use of extracorporeal support systems is found in Chapter 41, “Drug Dosing in Special ICU Populations.” In all cases, patients should be closely monitored for signs of both efficacy and toxicity. A summary of the guidelines for drug dosing in ALF is presented in Table 28.7.

LEARNING OBJECTIVES

1. Differentiate between the typical presentation of upper and lower gastrointestinal (GI) bleeding.

2. Identify risk factors for clinically relevant GI bleeding in the intensive care unit.

3. Identify measures for the primary prevention of both upper and lower GI bleeding.

4. Individualize the reversal of drug-associated bleeding according to the likely offending agent.

5. Understand the role of acid-suppressive therapy and other hemostatic agents in the acute management of clinically significant GI bleeding.

6. Identify strategies for the secondary prevention of GI bleeding using risk stratification tools.

7. Understand the role of Helicobacter pylori screening and treatment in the setting of peptic ulcer disease.

8. Consider the risks and benefits of reintroducing anticoagulation, antiplatelet therapies, and NSAIDs.
INTRODUCTION

Acute upper and lower gastrointestinal bleeding (GI) are common conditions that require admission to the intensive care unit (ICU) or complicate the stay of patients admitted for other ailments. Despite advances in endoscopic and pharmacologic therapies, morbidity and mortality associated with upper and lower GI bleeding remain significant.\textsuperscript{1,2} In addition, the epidemiology of GI bleeding is evolving, given that a decrease in the incidence of upper GI bleeding and an increase in the incidence of lower GI bleeding have occurred in recent years.\textsuperscript{3}

Peptic ulcer disease remains the most common cause of GI bleeding. Nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin use as well as Helicobacter pylori infection are the primary causes.\textsuperscript{4,5} Lower GI bleeding is not as well studied as upper GI bleeding and remains likely underreported because many patients with bleeding remain without medical evaluation.\textsuperscript{6} Three levels of bleeding, ranging

from occult to moderate to severe, show the gravity of the disease. Diverticular disease is the most common cause of lower GI bleeding. In the critically ill, mesenteric ischemia and ischemic colitis are also common. Admission to the ICU for upper and lower GI bleeding is determined by the presence of hypotension, respiratory failure, cardiac ischemia, and new neurological dysfunction.

**CLINICAL PRESENTATION AND PATHOPHYSIOLOGY**

**Upper GI Bleeding**

Upper GI bleeding is defined as bleeding originating from the esophagus, stomach, or duodenum. Clinically important upper GI bleeding has been defined as macroscopic bleeding causing hemodynamic instability or necessitating blood transfusions. The most common presentations for upper GI bleeding are hematemesis, vomiting of fresh blood or coffee ground–like matter, and melena, which are black and tarry stools. Hematochezia, the passage of fresh blood with stools, may also be present in upper GI bleeding, most often when the bleeding is clinically significant. Common causes of upper GI bleeding include duodenal and gastric ulcer disease, erosive gastritis, esophageal variceal hemorrhage, and Mallory-Weiss tears (Box 29.1). In critically ill patients, stress-related mucosal disease (SRMD) is a common cause of ICU-acquired GI bleeding. Because significant bleeding reduces intravascular volume, it commonly presents with systemic symptoms such as resting tachycardia and hypotension or postural changes in blood pressure.

The pathophysiology of upper GI bleeding varies according to cause. Peptic ulcer disease is mainly caused by H. pylori infection. This gram-negative bacteria causes inflammation of the gastric and duodenal mucosa, which renders the mucosa more vulnerable to ulceration that can progress to the submucosa and damage arterial walls. The NSAIDs inhibit cyclooxygenase and modify prostaglandin production, thereby reducing the protection provided by the mucosa. In much the same way as H. pylori, NSAID use enables the formation of
mucosal ulcerations. Whereas H. pylori is responsible for more duodenal than gastric ulcers, NSAIDs have a more predominant effect on the stomach than on the duodenum.\textsuperscript{7} In the presence of both pathologic factors, the risk of ulceration seems to be additive.\textsuperscript{11} In addition, drugs that inhibit platelet aggregation (e.g., selective serotonin reuptake inhibitors or the coagulation cascade) increase the risk of GI bleeding in patients with preexisting mucosal damage.\textsuperscript{12}

Stress-related mucosal disease develops when critical illness induces a reduction in cardiac output, catecholamine-induced vasoconstriction, and proinflammatory cytokine release. The ensuing splanchnic hypoperfusion induces an imbalance between oxygen delivery and demand, inducing mucosal ischemia and a reduction in the capacity to neutralize hydrogen ions. A reduction in motility as well as a reduction in protective mucus production also contribute to the development of SRMD (Figure 29.1).\textsuperscript{13} The initial mucosal injury can remain superficial and lead to occult blood loss from the bleeding of mucosal capillaries. In certain cases, the injury can evolve to larger vessels and cause severe bleeding.

Mallory-Weiss tears are longitudinal lacerations to the mucosa of the stomach cardia or at the gastroesophageal junction that are caused by a sudden increase in intra-abdominal pressure, which is most often caused by vomiting.\textsuperscript{14} Initially described in patients with acute alcohol ingestion, Mallory-Weiss tears are often described in other conditions associated with repeated vomiting (i.e., chemotherapy, gastroenteritis). Esophageal varices develop as the result of portal hypertension secondary to liver cirrhosis and can be life threatening. Because the management and outcomes are different from those for other causes of upper GI bleeding, this subject is beyond the scope of this chapter and will be covered with liver diseases (Chapter 28).

**Lower GI Bleeding**

Lower GI bleeding is defined as bleeding from the gut distal to the ligament of Treitz. Hematochezia is the most common feature, but melena can also be present, especially in patients with bleeds originating from the distal small bowel and colon. The most common
causes of lower GI bleeding are colonic diverticulosis, colorectal malignancy, inflammatory bowel disease, anorectal disease, mesenteric ischemia, and ischemic colitis.\textsuperscript{2,15,16} Colonic diverticulosis develops with age as the colonic wall weakens, creating protrusions, usually at the insertion of the vasa recta artery.\textsuperscript{17} Bleeding is secondary to the rupture of this artery and spontaneously resolves in many cases. However, in 3\%–5\% of cases, bleeding can be important.\textsuperscript{18} Clinically significant bleeding secondary to diverticular disease has been associated with diabetes, hyper-tension, anticoagulation, and ischemic heart disease.\textsuperscript{18} Mesenteric ischemia and ischemic colitis arise from an imbalance between oxygen supply and demand in the small bowel and colon. Thrombosis, emboli, and vasoconstriction caused by medications such as vasopressors are responsible for mesenteric ischemia.\textsuperscript{7} The main causes of mesenteric ischemia are arterial embolism, arterial thrombosis, small vessel occlusion, and venous thrombosis. Atherosclerosis and cardiac disease (valvular disease, atrial arrhythmias, ventricular dilatation) are important risk factors.\textsuperscript{19} A hypercoagulable state, hypovolemia, and previous arterial emboli are also associated with mesenteric ischemia.\textsuperscript{20} Ischemic colitis is caused by reduced perfusion to the colon, and bleeding occurs as the result of mucosal necrosis. Colon carcinomas represent an important proportion of rectal bleeding in older patients. These tumors tend to bleed much more slowly.\textsuperscript{21} Crohn disease, ulcerative colitis, hemorrhoids, and anal fissures are other common causes of lower GI bleeding.

### Epidemicology

The reported incidence of upper GI bleeding leading to hospitalization varies from 37 to 172 per 100,000 adults.\(^1\)\(^,\)\(^2\)\(^2\)\(^2\) Differences in reported incidents are attributable to variations in studied populations and study periods. Duodenal and gastric ulcers represent the most common etiologies of upper GI bleeds, followed by Mallory-Weiss tears and esophagitis.\(^2\)\(^2\)\(^2\)\(^2\) The reported incidence of lower GI bleeding in the general population varies from 22 to 87 per 100,000 adults.\(^2\)\(^2\)\(^2\)\(^2\)

### Peptic Ulcer Disease

The hospitalization rates for peptic ulcer bleeding have been declining in recent years because of reduced H. pylori infection rates and increased use of proton pump inhibitors (PPIs).\(^2\)\(^3\)\(^,\)\(^4\) In the United States, the age/sex-adjusted incidence of peptic ulcer bleeding decreased from 41.8 to 35.7 per 100,000 between 2001 and 2009.\(^2\)\(^5\) In Spain, the incidence of hospitalization for upper GI bleeding decreased from 54.6 in 1996 to 25.8 per 100,000 person-years in 2006.\(^2\)\(^3\)

### Stress-Related Mucosal Disease

**Mallory-Weiss tears (4%–7%)**

**Less common**

- Malignancy (2%–4%)
- No diagnosis (8%–25%)
- Others

---

Endoscopic studies suggest that most critically ill patients develop gastric erosions related to SRMD during the ICU stay. However, the incidence of clinically important upper GI bleeding, defined as the presence of hematemesis, bloody GI aspirate, or melena, is 1.5%–2.8% in the critically ill. In patients with risk factors such as mechanical ventilation and coagulopathy, the incidence increases to 3.7%. Nevertheless, these data were published 15–20 years ago, and because the treatment of critically ill patients has evolved during the past decades, the incidence of SRMD is declining. Contemporary studies tend to suggest a decline in the incidence of clinically important upper GI bleeding.

**Mallory-Weiss Syndrome**

Mallory-Weiss tears are a common cause of upper GI bleeding and represent 3%–12% of cases. However, most cases resolve spontaneously, and clinically significant bleeding is rare.

**Lower GI Bleeding**

The incidence of lower GI bleeding requiring hospitalization, for both acute and occult bleeding, is reported to be 20–33 per 100,000 in studies from the United States and Spain. A recent population-based study of patients undergoing colonoscopy in Iceland reported a crude incidence of 87 per 100,000 per year.

**RISK FACTORS**

The risk of upper GI bleeding is significantly increased in older age. Studies have reported a 4-fold increase in the risk in patients 75 years and older. Nonsteroidal anti-inflammatory drugs are a major risk factor for upper GI bleeding caused by peptic ulcers. Although all NSAIDs are associated with an increased risk of upper GI bleeding, traditional NSAIDs are associated with a greater risk of upper GI bleeding than are cyclooxygenase-2 (COX-2) selective inhibitors.
Among the traditional NSAIDs, ibuprofen seems to have the best safety profile, whereas ketorolac has the worst.\textsuperscript{33} As previously mentioned, \textit{H. pylori} also plays an important role in the pathogenesis and risk of developing upper GI bleeding.

In patients with GI bleeding, risk factors identifiable on admission that are associated with an increased risk of developing acute critical illness include coagulopathy, hypotension, neurologic dysfunction, and an Acute Physiology and Chronic Health Evaluation II (APACHE II) score greater than 15.\textsuperscript{34} When comparing upper and lower GI bleeding, male sex and NSAID use have been associated with an increased risk of upper GI bleeding, whereas the number of comorbidities and a recent diagnosis were associated with an increased risk of lower GI bleeding.\textsuperscript{31}

\textbf{Peptic Ulcer Disease}

\textit{H. pylori} and NSAIDs are the two main causes of peptic ulcer disease. As rates of \textit{H. pylori}–associated peptic ulcer disease have declined, some studies have reported an increase in low-dose-aspirin–associated disease.\textsuperscript{35} Several demographic and lifestyle risk factors have been associated with complicated peptic ulcer disease. Older age, male sex, significant alcohol consumption, tobacco use, comorbidities, and psychological stress have been linked, although not always consistently across studies, to an increased risk of complicated peptic ulcer disease.\textsuperscript{36,37} Serotonin reuptake inhibitors have also been associated with a modest increase in upper GI bleeding, which significantly increases in the presence of NSAID use.\textsuperscript{38} Patients at high risk of NSAID-associated GI bleeding are those with a history of complicated ulcer and two other risk factors (age older than 65 years, high-dose NSAID therapy, and concurrent use of aspirin, corticosteroids, or anticoagulants).\textsuperscript{39} Patients with one risk factor or a history of uncomplicated ulcer are considered at moderate risk.

\textbf{Stress-Related Mucosal Disease}
Historically, SRMD has been associated with head trauma (Cushing ulcers) and major burns (Curling ulcers). In the critically ill, the risk of SRMD has been associated with respiratory failure and coagulopathy. The presence of both factors has been associated with a 3.7% incidence of GI bleeding compared with 0.1% in patients without these risk factors. Other factors commonly associated with SRMD include hypotension, sepsis, surgery, hepatic failure, and renal failure. Receiving enteral nutrition is an independent protective factor, even in the presence of ranitidine.

**Mallory-Weiss Syndrome**

Mallory and Weiss first described the condition in 1929 in the setting of acute alcohol ingestion. Other factors that have been associated with Mallory-Weiss tears include NSAID use, anticoagulation, and the presence of hiatal hernia.

**Lower GI Bleeding**

As the incidence of diverticulosis and ischemia increases with age, so does the incidence of lower GI bleeding. In a recent study, the age-standardized incidence rate of acute lower GI bleeding increased from 18 per 100,000 per year in patients 25–39 years of age to 187 and 690 per 100,000 per year in patients 60–79 and 80–105 years of age, respectively. Male sex has been inconsistently associated with an increased risk of lower GI bleeding. The presence of comorbidities and the use of NSAIDs, antiplatelet agents including aspirin, and anticoagulants have also been associated with an increased risk of lower GI bleeding. Rebleeding occurs more often in older patients and those exposed to NSAIDs and nonaspirin antiplatelet agents. Finally, independent risk factors for clinically significant (compared with nonsignificant) bleeding include age, non-hemorrhoidal bleeding, and combined use of aspirin and warfarin.
OUTCOMES

The consequences and complications associated with upper and lower GI bleeding are broad and include anemia, emergency surgery, cardiac ischemia, and hospitalization, as well as an increased risk of death.\textsuperscript{43} The mortality associated with upper GI bleeding has been declining in recent years.\textsuperscript{9} A recent database study from the United States reported a 2.45\% case fatality for upper GI bleeding.\textsuperscript{25} Intensive care unit–acquired GI bleeding in mechanically ventilated patients has been associated with an increased risk of death.\textsuperscript{43} Clinically important upper GI bleeding in critically ill patients has also been associated with an increase in length of stay secondary to bleeding of 3.8–7.9 days.\textsuperscript{43}

Many risk factors are associated with unfavorable outcomes in patients with an upper GI bleed, including increasing age, APACHE II score, comorbid conditions, liver disease, hypotension or shock on presentation, hospitalization, and rebleeding.\textsuperscript{1,32,44,45} Rebleeding occurs in 7\%–16\% of patients after endoscopic treatment and has a major influence on the outcomes of upper GI bleeding.\textsuperscript{1,10} The reported mortality rate in patients with recurrent bleeding is greater than 30\%.\textsuperscript{46}

The mortality risk appears to be similar when comparing peptic ulcer disease with non-ulcer causes of upper GI hemorrhage.\textsuperscript{47,48} In the specific case of Mallory-Weiss syndrome, age older than 65 years and comorbidities are independently associated with an increased risk of mortality.\textsuperscript{48}

In patients with lower GI bleeding, the reported mortality is 2.2\%–8.8\%.\textsuperscript{16,31,49,50} When patients with lower GI bleeding were compared with those with upper GI bleeding, one study reported a greater risk of mortality (8.8\% vs. 5.5\%) and an increased length of hospitalization (11.6 vs. 7.7 days).\textsuperscript{31} Risk factors for unfavorable outcomes in patients with a lower GI bleed include advanced age, hemodynamic instability, comorbid conditions, already being hospitalized, and use of certain drugs such as aspirin and NSAIDs.\textsuperscript{2}

PREVENTION OF GI BLEEDING
Stress Ulcer Prophylaxis

Although clinically significant GI bleeding rarely occurs in critically ill patients, strategies to prevent stress ulcers have long been advocated in high-risk patients. Stress ulcer prophylaxis is aimed at reducing the risk of clinically important upper GI bleeding and consequently improving outcomes such as length of stay in critically ill patients. Stress ulcer prophylaxis is recommended in patients with risk factors for SRMD, notably coagulopathy and mechanical ventilation for more than 48 hours. Several pharmacologic agents have been advocated for preventing stress ulcers, including antacids, sucralfate, histamine-2 receptor blockers (H\textsubscript{2}RBs), and PPIs. Antacids, titrated to obtain a gastric pH above 3.5, reduced GI bleeding. Frequent administration and the risk of drug interactions significantly limit antacid use. Sucralfate, which protects the gastric mucosa by forming a cytoprotective barrier, reduces ulcerations compared with placebo. Histamine-2 receptor blockers reduce gastric acid and secretions by competitively inhibiting histamine binding to parietal cell receptors. In a pivotal clinical trial, H\textsubscript{2}RBs reduced the relative and absolute risks of clinically important GI bleeding by 66% and 2.1%, respectively, compared with sucralfate. Proton pump inhibitors increase gastric pH by inactivating the parietal cell H\textsuperscript{+}/K\textsuperscript{+} ATPase enzyme. Although no large and adequately powered studies compare PPIs with H\textsubscript{2}RBs, a recent meta-analysis suggests that PPIs are more effective at reducing the risk of clinically significant GI bleeding. In North America, observational studies have shown that PPIs are the most commonly used agents in critically ill patients. Although H\textsubscript{2}RBs and PPIs reduce the risk of clinically significant GI bleeding, a corresponding impact on mortality has not been shown.

The use of stress ulcer prophylaxis is not without risks. Using H\textsubscript{2}RBs and PPIs in critically ill patients may be associated with infectious complications, particularly Clostridium difficile–associated diarrhea and nosocomial pneumonia. Given that gastric acid contents are protective against bacterial survival in the stomach, there is evidence that alkalizing agents such as PPIs and H\textsubscript{2}RBs promote bacterial
overgrowth. However, evidence from randomized controlled trials supporting these associations is limited because nosocomial infections, and especially C. difficile infections, are rarely reported. In a recent meta-analysis comparing PPIs with H$_2$RBs, investigators of eight trials reported on the risk of ventilator-associated pneumonia and found no difference in the risk of nosocomial pneumonia. However, no studies reported on the risk of C. difficile infections. Several observational studies have assessed the association between PPI or H$_2$RB use and the risk of developing nosocomial pneumonia and C. difficile–associated diarrhea. Some studies of critically ill patients have reported an independent increased risk of nosocomial pneumonia with PPI use, whereas others have not found this association. Different patient populations, differing definitions of nosocomial pneumonia, and residual confounding may account for these different findings. The risk of C. difficile–associated diarrhea is increased with PPI use in several observational studies, but not in others. Variations in endemicity, susceptibility of populations, and presence of other risk factors such as the use of broad-spectrum antibiotics may explain these contrasting results. In addition, patients taking H$_2$RBs seem to be at lower risk of contracting C. difficile–associated diarrhea compared with those taking PPIs.

Because using H$_2$RBs and PPIs for stress ulcer prophylaxis has been questioned for efficacy and safety reasons, enteral nutrition alone has been suggested as a potential alternative to acid-suppressive therapies. Studies have suggested that enteral nutrition improves mucosal blood flow and may increase gastric pH. Because of observational data, some authors suggest using enteral nutrition as the only stress ulcer prophylaxis in most critically ill patients (excluding trauma and burn patients). However, no randomized controlled trials have directly compared enteral nutrition with H$_2$RBs or PPIs.

**Prevention of Drug-Induced/Associated GI Bleeding**

Because NSAID, COX-2 inhibitor, and aspirin users have an increased risk of GI bleeding, mucosal protection strategies are used to prevent
the development of peptic ulceration. Proton pump inhibitors, high-dose 
$H_2$RBs, and misoprostol all reduce the risk of peptic ulcers. The 
COX-2 inhibitors are associated with a lower incidence of peptic ulcers 
than are the NSAIDs. However, the combined use of low-dose aspirin 
and COX-2 inhibitors is associated with the same risk of GI bleeding 
as the use of NSAIDs. In addition, this protective effect of COX-2 
inhibitors is undermined by an increased risk of myocardial infarction. 
Hence, recent recommendations for preventing NSAID-related ulcer 
complications consider both the GI risk (low, moderate, or high) and 
the cardiovascular risk (requirement of aspirin for preventing serious 
cardiovascular events). Risk factors for NSAID GI toxicity include age 
older than 65 years, high-dose NSAID therapy, a history of 
uncomplicated ulcer, and concurrent use of aspirin, corticosteroids, or 
anticoagulants. Patients with a history of a complicated ulcer 
(especially recent) or more than two risk factors are considered at high 
GI bleeding risk. Patients with one or two risk factors are considered 
at moderate GI bleeding risk. Patients with no risk factors are 
considered at low GI bleeding risk.

In patients at high cardiovascular risk, naproxen has been advocated 
as the NSAID of choice in combination with a PPI or misoprostol. In 
patients who are also at high GI risk, avoiding NSAIDs and COX-2 
inhibitors is recommended. In patients at low cardiovascular risk, using 
an NSAID alone is acceptable if the risk of GI bleeding is low. 
However, a PPI or misoprostol is suggested in patients at moderate GI 
risk. Finally, in patients at low cardiovascular risk and high risk of GI 
toxicity, avoiding NSAIDs, if possible, or using a COX-2 inhibitor 
combined with a PPI or misoprostol is recommended.

**APPROACH TO DIAGNOSIS**

Data gathered from the history, physical assessment, and laboratory 
tests dictate the need for resuscitation, describe the severity of 
bleeding, identify the potential sources of bleeding, and facilitate the 
triage of further diagnostic or therapeutic interventions. The initial 
assessment begins with an evaluation of hemodynamic stability.
Patients presenting with hypotension, evidence of end-organ ischemia, or large volumes of blood loss need immediate resuscitation. In the clinical setting, most patients who present with upper GI bleeding have hematemesis or melena. Those presenting with melena or hematochezia are typically thought to have lower GI bleeding.

**Upper GI Bleeding**

Presentation with frank hematemesis typically suggests more severe bleeding than presentation with coffee ground emesis. Melena usually indicates upper GI bleeding, but it can also occur with bleeding from the distal small bowel or the proximal colon. Hematochezia usually indicates GI bleeding from the colon, but it can occur with massive upper GI bleeding. The history obtained from the patient or family member can also be valuable. Patients with a history of GI bleeding typically bleed from the same lesion. The approach to diagnosis and management may also be affected by a patient history of liver disease (and knowledge of existing varices or portal hypertension), peptic ulcer disease and its previous investigations, previous H. pylori treatment, malignancy, or alcohol abuse. A medication history specifically looking for use of NSAIDs, aspirin, anticoagulants, antiplatelet agents, and corticosteroids helps identify risk and potential causative factors. Patients taking iron supplements or bismuth-containing products may present with black stools, which can be mistaken for melena.

Patients presenting with hemodynamic instability need immediate resuscitation with crystalloid fluids and blood products. Patients may also present with orthostatic hypo-tension, confusion, tachycardia, supraventricular tachyarrhythmias, and cold or mottled extremities. The symptoms reported immediately preceding the acute event can also help predict the source of bleeding. Epigastric or right upper quadrant pain can be indicative of peptic ulcer bleeding, whereas reflux, dysphagia, and odynophagia may predict esophageal ulceration. Intractable vomiting, retching, or even coughing can precede hemorrhage from a Mallory-Weiss tear, and cachexia or significant involuntary weight loss may suggest malignancy. Laboratory tests
should include a complete blood cell count, serum electrolytes and chemistries, liver function tests, and coagulation studies. Initial hemoglobin values usually appear normal as patients are losing whole blood. With resuscitation and time, hemoglobin concentrations usually drop within 24 hours.

Lower GI Bleeding
Patients with lower GI bleeding typically present with hematochezia or (rarely) melena if they have right-sided colonic bleeding. Patient histories, physical assessments, and laboratory investigations play a similar role in suspected upper GI bleeding. The goals of initial assessment are to assess the severity of bleeding, triage the patient to the appropriate care setting, initiate resuscitation, and consider the potential source of bleeding. After resuscitation, diagnostic and potentially therapeutic interventions such as colonoscopy may be warranted.

INITIAL MANAGEMENT

Airway and Vascular Access
All patients with GI bleeding and hemodynamic instability should be admitted to the ICU for resuscitation, cardiac monitoring, and pulse oximetry. All patients should receive supplemental oxygen, and patients with decreased levels of consciousness, ongoing hematemesis, or respiratory distress may need endotracheal intubation. Intubation not only helps facilitate endoscopy, but also protects against the risk of aspiration. All patients should receive either a central venous catheter or two large-bore peripheral venous catheters for resuscitation.

Fluid Resuscitation and Blood Transfusion
Hemodynamic stabilization before endoscopy improves patient outcomes. Bleeding and/or hypotensive patients should receive
intravenous crystalloid fluids such as normal saline or lactated Ringer solution (i.e., boluses of 500 mL over 30 minutes or less) while being typed and cross-matched for blood transfusions. The frequency and number of fluid boluses should be evaluated in the context of blood pressure response, acknowledging that over-resuscitation may also be harmful. Crystalloid resuscitation causes a dilution of the blood remaining in the vascular space and may result in increased bleeding from clot destabilization and dilution of factors that allow new clot formation. Smaller, more frequent, boluses are more likely to result in the smallest effective volume administered to achieve hemodynamic stabilization.

Beyond evidence of massive hemorrhage, the decision to transfuse blood should be directed by measured hemoglobin concentrations. A randomized controlled trial of 921 adults with acute upper GI bleeding suggested that a restrictive transfusion practice is associated with improved outcomes compared with a liberal transfusion practice. Patients in this trial were randomized to receive blood transfusions when hemoglobin concentrations fell below 7 g/dL (conservative arm) or 9 g/dL (liberal arm). Of note, patients with massive hemorrhage, low risk of further bleeding, acute coronary syndrome, or significant cardiovascular disease were excluded. About one-half of the patients in the study had peptic ulcer disease, whereas one-fourth had variceal bleeding. The conservative transfusion strategy was associated with a lower mortality (hazard ratio 0.55; 95% confidence interval, 0.33–0.92), less rebleeding, and fewer complications. All patients in this study underwent early endoscopy. In addition to blood, transfusion of fresh frozen plasma (FFP) is indicated for patients with significant coagulopathy (i.e., international normalized ratio [INR] greater than 1.5). Similarly, platelet transfusions are indicated for patients presenting with thrombocytopenia (i.e., platelet count less than 50,000/mm$^3$).

**Reversal of Drug-Associated Bleeding**

Whenever possible, drugs implicated in causing or facilitating GI
bleeding should be discontinued. In some cases, the effects of these drugs should be reversed (Table 29.1). The original indication for the drug in question, however, must be considered, and the risks and benefits of discontinuation/reversal must be considered. In some cases, consultation with a specialist may be warranted to fully assess the risks versus the benefits (i.e., reversal of a low-molecular-weight heparin [LMWH] for treatment of pulmonary embolism). Anti-inflammatory drugs such as NSAIDs and aspirin should be held to prevent further irritation to exposed ulcers and/or blood vessels.

If safe to do so, vitamin K antagonists (i.e., warfarin) should be reversed with FFP rather than vitamin K because the onset of activity with vitamin K can be delayed as long as 6–24 hours. Prothrombin complex concentrates (PCCs) are also an alternative to FFP and may be considered together with vitamin K as an alternative to FFP. Four-factor PCCs such as Octaplex or Kcentra contain clotting factors II, VII, IX, and X and are prepared from human plasma. Although vitamin K administered intravenously is rarely associated with anaphylactic reactions, the onset of activity is faster than with other routes of administration and is more desirable in acute or major bleeding.

DDAVP = desmopressin; FFP = fresh frozen plasma; IV = intravenous(ly); LMWH = low-molecular-weight heparin; NSAID = nonsteroidal anti-inflammatory drug; PCC = prothrombin complex concentrate.
Anticoagulation with heparin or LMWH can be reversed with protamine sulfate, which binds to and inactivates heparin molecules that are subsequently cleared by the reticular endothelial system. Anaphylactic reactions, hypotension, and bronchospasm can occur because of histamine release, but these adverse effects are rare and typically transient. Furthermore, in the absence of heparin or at excessive doses, protamine has weak antiplatelet and anticoagulant activity. The clinical importance of these effects in patients who are bleeding is not well established, but they are easily avoided using the maximum dose of 50 mg. The time elapsed since the last exposure to heparin should also be considered because less protamine is required if some of the heparin has already been eliminated. Reversal of anticoagulation from unfractionated heparin is more predictable than from LMWH because protamine sulfate only partly reverses the effects of LMWH. Some studies suggest that protamine sulfate reverses only 60% of the antifactor Xa (anti-Xa) activity of LMWH.

Reversal of anticoagulation from new oral anticoagulants (i.e., dabigatran, rivaroxaban, and apixaban) is a greater challenge as we wait for antidotes that are currently being developed and evaluated in clinical trials. Rivaroxaban and apixaban are inhibitors of factor Xa, and dabigatran is a direct thrombin inhibitor. Dabigatran has the longest half-life at 14–17 hours, whereas the half-lives of rivaroxaban and apixaban are 7–11 hours and 8–14 hours, respectively. Idarucizumab, a monoclonal antibody with a greater affinity for dabigatran than thrombin, may be the first antidote approved for use. Initial evidence suggests that idarucizumab rapidly and completely reverses the effects of dabigatran. Andexanet, a recombinant, modified factor Xa molecule, is currently being evaluated for the reversal of anticoagulation from factor Xa inhibitors such as rivaroxaban and apixaban. Phase III trials are currently under way. Although these agents represent promising options for patients who are bleeding, rapid reversal strategies are still required until these agents become available. Several prohemostatic agents or coagulation factor concentrates have been suggested, but human evidence is limited for the efficacy of these treatments. The PCCs (e.g., Octaplex and
Kcentra) and the activated PCCs (e.g., FEIBA) can be tried to reverse the effects, with the choice of agent dependent on availability. The PCCs appear to be less effective than the activated PCCs in reversing anticoagulation with dabigatran compared with rivaroxaban in healthy volunteers and ex vivo studies. Evidence for activated factor VIIa is less compelling. Human evidence is limited to describe the efficacy and safety of these products in this setting.

Platelet transfusions are commonly administered in the setting of GI bleeding if patients are on antiplatelet agents, but this practice is not evidence based. The role of platelet transfusion is not well defined, but platelets may be indicated in patients on antiplatelet therapy (i.e., aspirin or clopidogrel). The risks of reversal must be considered according to the original indication of the drug (i.e., prevention of acute coronary syndrome or maintenance of stent patency). Desmopressin has also been used in this setting because its presumed mechanism of action is the release of von Willebrand factor from endothelial cells, which in turn can stabilize platelets and promote binding to the endothelium. Bleeding times are shortened with desmopressin in healthy volunteers taking aspirin or ticlopidine, but evidence in patients who are bleeding is limited.

**Hemostatic Medications**

Early initiation of acid-suppressive therapy in upper GI bleeding serves two purposes: (1) neutralization of gastric acid can improve the stabilization of blood clots and (2) continued therapy reduces rebleeding rates, hospital lengths of stay, and the need for blood transfusions, particularly in peptic ulcer disease treated endoscopically (Table 29.2). The role of acid-suppressive therapy before endoscopy in un-differentiated bleeding is a source of controversy because of conflicting findings in clinical trials. A meta-analysis of six randomized controlled trials suggests that although there is no evidence that PPI therapy before endoscopy affects outcomes like mortality, rebleeding, or need for surgery, it reduces the stigmata of recent hemorrhage and subsequently the need for endoscopic therapy during
Proton pump inhibitors are preferred to H₂RAs and traditionally have been initiated as high-dose continuous infusions. Recent evidence suggests that high-dose continuous infusions are associated with no better outcomes than intermittent dosing strategies (i.e., intravenous pantoprazole or esomeprazole 40 mg twice daily). However, some still advocate for high-dose therapy in patients with high-risk stigmata (i.e., Rockall scores greater than 6). There is no evidence for the use of acid-suppressive therapy in the acute management of lower GI bleeding.

Tranexamic acid is an antifibrinolytic agent often used in surgical settings as a hemostatic drug. A recent systematic review suggests that, in the absence of acid-suppressive therapy and endoscopic treatment, a mortality benefit is associated with tranexamic acid. This effect did not occur, however, when only studies with patients who received conventional therapy were retained. Given that acid-suppressive therapy plus endoscopic intervention (when indicated) is the standard of care, tranexamic acid currently has no role in the treatment of upper GI bleeding.

Prokinetic agents such as erythromycin and metoclopramide have also been studied in upper GI bleeding. Pro-kinetic therapy before endoscopy improves gastric emptying of blood, clots, and food to improve visualization at the time of endoscopy. Results from a meta-analysis of small trials suggest that both erythromycin and metoclopramide reduce the need for repeat endoscopy but that they affect other clinical outcomes. There are more trials with erythromycin than with metoclopramide. Meta-analyses of erythromycin studies consistently show a reduced need for second endoscopy, but these meta-analyses also show inconsistent effects on other meaningful clinical outcomes compared with placebo. Despite these limitations, erythromycin may be considered before endoscopy in patients with upper GI bleeding.

Vasopressin, somatostatin, and their synthetic analogs (terlipressin and octreotide, respectively) are vasoactive medications that reduce splanchnic blood flow. They are used to achieve hemostasis in variceal hemorrhage. Theoretically, the same mechanism would be beneficial in
Role of Endoscopy/Colonoscopy and Other Invasive Interventions

Early endoscopy (within 24 hours) is advocated for most patients to identify the source of bleeding, to assist in the triage of further interventions and patient management, and for use therapeutically to achieve hemostasis. For diagnosis, endoscopy is the definitive test. Endoscopic findings are typically described using the Forrest classification (class Ia: spurting hemorrhage; class Ib: oozing hemorrhage; class IIa: nonbleeding visible vessel; class IIb: adherent clot; class IIc: flat pigmented spot; class III: clean ulcer base).\textsuperscript{104} The lesion’s appearance can help determine both the patient’s risk of rebleeding and the need for specific interventions. Although early endoscopy is recommended for most patients with hematemesis, its impact on the outcome is controversial. Studies describing its effect on resource use and patient outcome are conflicting.\textsuperscript{105-108} Endoscopic treatments aimed at controlling bleeding may include injection of epinephrine, thermal coagulation, use of hemostatic clips or fibrin sealants, argon plasma coagulation, or a combination of these therapies.\textsuperscript{109} Standard approaches to therapy usually involve a combination of treatments, depending on the location of the lesion and the endoscopist’s preference.

Colonoscopy is the definitive test for lower GI bleeding once upper GI bleeding has been ruled out. Colonoscopy is used to visualize and assess the source and severity of bleeding, obtain samples for pathology, and provide therapeutic intervention. Urgent colonoscopy often is done without mechanical bowel preparation, which limits the
ability to visualize the source of bleeding. If a patient is hemodynamically stable after resuscitation, colonoscopy is often delayed to allow time for adequate bowel preparation (i.e., enteral administration of 4 L of polyethylene glycol). Similar to early endoscopy for upper GI bleeding, early colonoscopy has been associated with better triage of patients, improved resource use, and a reduction in the risk of rebleeding. However, these findings have not been consistent in clinical trials. Other diagnostic tests such as radionuclide imaging and angiography can also be used to identify sources of bleeding. These noninvasive or minimally invasive tests require active bleeding at the time of the study to detect the source. These strategies are typically reserved for patients in whom colonoscopy is either not feasible because of severe bleeding or nondiagnostic with persistent or intermittent bleeding.

In the past, surgery was the mainstay of treatment for both upper and lower GI bleeding. However, early endoscopic intervention has significantly reduced the need for more invasive operations. Now, surgery is usually reserved for failed endoscopic therapies with persistent bleeding, hemodynamic instability caused by persistent or recurrent bleeding despite aggressive resuscitation, or visceral perforation. Interventional angiography with transarterial embolization is another option recommended ahead of surgery for persistent or recurrent bleeding despite endoscopy/colonoscopy.

<th>Table 29.2</th>
<th>Drug Therapy for Hemostasis and Prevention of Rebleeding</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Indication</strong></td>
<td><strong>Drug Therapy</strong></td>
</tr>
<tr>
<td>High-dose IV PPI therapy: Pantoprazole 80 mg IV bolus, followed by 8 mg/hr for 72 hr or Esomeprazole 80 mg IV bolus, followed by 8 mg/hr for 72 hr</td>
<td>Intermittent dosing is noninferior to high-dose therapy, although some still advocate the high-dose regimens for patients presenting with high-risk stigmata</td>
</tr>
</tbody>
</table>
### Intermittent-dose IV PPI therapy:
- Pantoprazole 40 mg IV BID

### Hemostasis
- Esomeprazole 40 mg IV BID
- Tranexamic acid 10 mg/kg IV QID or 1 g IV QID

Tranexamic acid most likely to be of benefit if endoscopy not available or delayed. Many different dosing regimens have been studied for a variety of indications. Others in addition to the recommendation here may also be appropriate.

- Tranexamic acid 10 mg/kg IV QID or 1 g IV QID

### Prevention of rebleeding
- Erythromycin 3 mg/kg IV over 20–30 min given 30–90 min before endoscopy

Erythromycin can enhance gastric emptying to facilitate endoscopy and may reduce the need for repeat endoscopy.

- Erythromycin 3 mg/kg IV over 20–30 min given 30–90 min before endoscopy

Octreotide 50–100 mcg IV bolus, followed by 25 mcg/hr for up to 3 days or until resolution of bleeding

According to small, low-quality studies, octreotide may reduce the risk of rebleeding in angiodysplasia-related GI bleeding. Similar small studies suggest a reduction in the duration of bleeding of endoscopically treated peptic ulcers.

- Octreotide 50–100 mcg IV bolus, followed by 25 mcg/hr for up to 3 days or until resolution of bleeding

### Oral PPI Therapy:
- Pantoprazole 40 mg BID
- Esomeprazole 40 mg QD
- Lansoprazole 30 mg BID
- Rabeprazole 20 mg BID
- Omeprazole 20 mg BID
- Dexlansoprazole 30 mg BID

Some evidence suggests that once-daily dosing is appropriate for patients at low risk of rebleeding (i.e., Rockall score < 6)

- Pantoprazole 40 mg BID
- Esomeprazole 40 mg QD
- Lansoprazole 30 mg BID
- Rabeprazole 20 mg BID
- Omeprazole 20 mg BID
- Dexlansoprazole 30 mg BID

BID = twice daily; PPI = proton pump inhibitor; QD = once daily; QID = four times daily.

---

**PREVENTION OF REBLEEDING**

Risk factors associated with upper GI rebleeding include the presence
of hemodynamic instability, hemoglobin nadirs of less than 10 g/L, active bleeding at the time of endoscopy, larger ulcer sizes, and ulcers in the posterior duodenal bulb or high lesser gastric curvature.  

**Risk Stratification**

Risk assessment using endoscopic, clinical, and laboratory findings can be useful in predicting the risk of rebleeding in patients presenting with acute upper GI bleeding. The two most commonly used scoring tools are the Rockall and Blatchford scores. The Rockall score incorporates risk factors such as age, presence of shock, comorbidities, and endoscopic findings (Table 29.3). A score of 2 or less is associated with a low risk of further bleeding or death. The advantages of the Blatchford score are that it does not require endoscopic findings and that it can be used earlier (Table 29.4). This score incorporates laboratory findings, vital signs, comorbidities, melena, and syncope. Scores range from 0 to 23, where a score of zero means that a patient has a low likelihood of requiring urgent endoscopy. 

**Acid-Suppressive Therapies**

A twice-daily intravenous PPI is part of the initial treatment of all patients presenting with upper GI bleeding. This therapy should be continued post-endoscopic treatment. In patients at high risk of rebleeding (i.e., Rockall score 6 or greater), the intravenous PPI may be changed to a twice-daily oral formulation 72 hours post-endoscopy. Patients at a lower risk of rebleeding may continue acid-suppressive therapy with only once-daily dosing of a PPI. Histamine-2 receptor blockers have also been studied in this setting, but they are inferior to PPIs. 

**Role of H. pylori Screening and Treatment in Peptic Ulcer Disease**

Antimicrobial treatment of H. pylori–infected individuals with upper GI
bleeding is associated with a significant reduction in ulcer relapse. Relapse rates in untreated infected individuals with duodenal ulcers are 65%–95%, whereas successful eradication with antibiotics reduces the risk of relapse to less than 10%. A meta-analysis comparing H. pylori eradication with antisecretory therapy alone suggests that five patients need to be treated to prevent recurrent bleeding episodes.

All patients presenting with upper GI bleeding should be tested for H. pylori. The American College of Gastroenterology recommends antral biopsy for urease testing as the test of choice in patients undergoing endoscopy. Other options include histology and culture. The advantage of bacterial culture is that, if isolated, antimicrobial sensitivities can be measured. The challenges are that it is not routinely available and that it is technically difficult. Patients who do not undergo endoscopy should be tested by noninvasive means such as breath testing or fecal antigen testing. Urea breath testing is an attractive noninvasive option in which patients are given a labeled carbon isotope by mouth; as the H. pylori lyse urea to produce carbon dioxide (CO₂) and ammonia, the tagged CO₂ can be detected in breath samples. Regardless of the test used, the positive predictive value is high (0.85–0.99), but the negative predictive value is low (0.45–0.75), particularly in the setting of acute upper GI bleeding. High false-negative results occur in the context of acute bleeding, PPI use, and preexisting antimicrobial therapy. Guideline recommendations suggest that negative H. pylori diagnostic tests in the acute setting should be repeated. The association between H. pylori and duodenal ulcers has traditionally been stronger than that between H. pylori and gastric ulcers, with original reports describing the prevalence of H. pylori infection with duodenal ulcers at 80%–95%. With such a high prevalence, empiric treatment of H. pylori with duodenal ulcers was common without diagnostic testing. Recent reports in the United States and parts of Europe suggest that this association is becoming less common (i.e., 50%–75%). Given this observation, it is prudent to confirm the diagnosis before treatment rather than treat empirically.

Scores of 3 or more are associated with mortality.

Many treatment regimens have been investigated for eradicating H. pylori. All of them involve a combination of antimicrobials with an antisecretory agent. Recommended therapies are provided in Table 29.5. Clarithromycin-based triple therapy and bismuth-based quadruple therapy have eradication rates of 70%–80%. The therapy durations recommended in the United States are usually longer (10–14 days) than those in other parts of the world (7–10 days). Data from meta-analyses suggest that eradication rates are higher with longer durations of therapy. This may be because antimicrobial resistance, particularly with clarithromycin and metronidazole, is increasing and is associated with treatment failure. Thus, it seems prudent to recommend longer durations of therapy. Treatment durations of less than 7 days are clearly inferior and are not recommended. Confirmation of eradication 4 weeks after treatment is strongly recommended, given the emergence of resistance and the availability of inexpensive, noninvasive testing (stool and breath testing).

**REINTRODUCTION OF ANTIMOAGULATION, ANTIPLATELET THERAPY, AND NSAIDS**

Patients presenting with drug-associated GI bleeding may be ineligible for permanent discontinuation of the offending drug. Patients taking NSAIDs for mild pain syndromes may be able to address their pain with non-NSAID alternatives (e.g., acetaminophen and other non-narcotic analgesics), but patients on antiplatelet or anticoagulant
therapy for cardiovascular or stroke prophylaxis will likely need to reinitiate therapy at some point after the bleeding episode resolves.

<sup>a</sup>PPI therapy may include pantoprazole 40 mg BID, lansoprazole 30 mg BID, omeprazole 20 mg BID, rabeprazole 20 mg BID, or esomeprazole 40 mg QD (note: esomeprazole is a delayed-release formulation and is dosed QD).

<sup>b</sup>The efficacy of sequential therapy has not been shown in North America. PPI = proton pump inhibitor.

Adapted from: Chey WD, Wong BC; Practice Parameters Committee of the American College of Gastroenterology. American College of Gastroenterology guideline on the
In NSAID-induced bleeding where anti-inflammatory therapy needs to be reintroduced, options may include reinitiating the NSAID in combination with a PPI or changing the NSAID to a COX-2 inhibitor either alone or in combination with a PPI. Other combination therapies including misoprostol, sucralfate, and H₂RAs have been studied, but they are either poorly tolerated or inferior to PPIs. Adding a PPI to an NSAID reduces the risk of recurrent bleeding, as does changing from an NSAID to a COX-2 inhibitor. The combination of a COX-2 inhibitor and a PPI is associated with the greatest risk reduction. Even in lower GI bleeding, discontinuing NSAID therapy has been associated with reduced re-bleeding rates.

Discontinuation or prolonged delays in reinitiating low-dose aspirin after a GI bleeding event are associated with significant cardiovascular morbidity. Discontinuation of prophylactic aspirin is associated with a 3-fold increase in major cardiac events, most of which occur 7–10 days after discontinuation. It is recommended that aspirin therapy be reintroduced as soon as the perceived risks of bleeding no longer outweigh the cardiovascular risks of withholding prophylaxis. Analyses of randomized controlled data suggest that immediately reinitroducing aspirin post-endoscopy is associated with negligible increases in rebleeding rates, whereas discontinuing aspirin is associated with an increased mortality at 8 weeks.

In patients who present with dual antiplatelet therapy or with a thienopyridine (e.g., clopidogrel, ticlopidine, or prasugrel), the decision about when to reinitiate is more complicated. Clinical practice guidelines suggest that antiplatelet therapy should be reinitiated as soon as possible post-endoscopy, provided there is no longer a suggestion of ongoing bleeding (usually 3–7 days post-endoscopy). Consultation with a cardiology specialist before endoscopy is recommended to fully assess the risks of withholding antiplatelet therapy. The risk of GI bleeding with clopidogrel is greater than with aspirin plus a PPI, and dual antiplatelet therapy has a 2- to 3-fold
increase in the risk of GI bleeding compared with aspirin alone.\textsuperscript{118,131} Adding a PPI to clopidogrel is associated with up to a 50% reduction in the risk of major bleeding, but this may also increase the risk of adverse cardiovascular events. All PPIs inhibit the cytochrome P450 (CYP) 2C19 necessary to activate clopidogrel to its active form. Pharmacokinetic studies confirm this interaction, but clinical studies fail to consistently show a meaningful clinical impact. Given the inconclusive nature of these data, clinical practice guidelines recommend concomitant PPI use in all patients on antiplatelet therapy for secondary prophylaxis of GI bleeding.\textsuperscript{131} The concerns of PPI use and clopidogrel do not extend to prasugrel because this drug does not require activation by CYP2C19.\textsuperscript{132}

Data regarding the optimal time and how to resume anticoagulation therapy are scant. Resumption of anticoagulant therapy with warfarin has been studied in patients with atrial fibrillation after a GI bleeding event. A retrospective cohort study of more than 1,300 patients with atrial fibrillation who were recovering from major GI bleeding found that reinitiating warfarin within 7–30 days after the GI bleed was associated with a reduced risk of thromboembolism and mortality compared with delaying reinitiation beyond 30 days.\textsuperscript{133}

**CONCLUSION**

Gastrointestinal bleeding is associated with significant morbidity and mortality, regardless of whether it occurs in the community or in the hospital. Although endoscopy is the cornerstone for diagnostic and therapeutic purposes, drug therapy continues to play an important role in reversal of anticoagulation, achievement of hemostasis, and prevention of rebleeding. This field is actively evolving, with ongoing trials evaluating hemostatic drugs like tranexamic acid and novel antidotes for newer anticoagulants as well as acid-suppressive therapy in the context of early endoscopy. Clinical pharmacists play an important role in assessing patients who are bleeding for providing antidotal therapies, selecting hemostatic agents, and promoting adherence to preventive drug therapy.

Section 7

Acute Pulmonary Disease
LEARNING OBJECTIVES

1. Discuss the epidemiology of pulmonary hypertension (PH) and pulmonary arterial hypertension (PAH).
2. Differentiate the different pathophysiologic mechanisms of PAH.
3. Discuss how molecular, cellular, and genetic mechanisms may play a future role in treatment of the critically ill patient.
4. Summarize the diagnosis and classification of PAH.
5. Detail the differing diagnostic scenarios and noninvasive/invasive tools that may be deployed for diagnosing PAH.
6. Review the medications used to treat PAH.
7. Evaluate the treatment options for patients with PAH in the intensive care unit (ICU).
8. Discuss the role of combination therapy in the treatment of PAH and considerations for the critically ill patient.
9. Summarize the adjunctive therapies used in PAH treatment and the level of evidence behind them.
10. Compare the different treatment guidelines published for the practitioner, and assess the evidence-based recommendations that can be used for ICU patients.
11. Explain the management of acutely decompensated patients
12. Discuss specific clinical pearls for treating patients in the ICU with PH/PAH as it relates to monitoring and adverse effect considerations.

**INTRODUCTION**

Pulmonary arterial hypertension (PAH) is a progressive disease caused by a narrowing of the blood vessels in the pulmonary vasculature. Pulmonary arterial hypertension is a rare subset of pulmonary hypertension (PH) that is differentiated from other types of PH as a primary process or in association with another condition.\(^1\) Pulmonary arterial hypertension is diagnosed by right heart catheterization (RHC) showing precapillary PH with a mean pulmonary artery pressure (mPAP) of 25 mm Hg or greater and a pulmonary capillary wedge pressure of less than 15 mm Hg.\(^2\) According to the patient’s clinical condition, PAH can be divided into various categories on the basis of severity of illness: stable and satisfactory, stable and not satisfactory, and unstable and deteriorating.\(^2\)
Management of PAH in the intensive care unit (ICU) may consist of diagnostic evaluation for patients with suspected PAH, treatment modifications for patients with PAH on chronic therapies, or a combination of worsening signs and symptoms in patients with PAH complicated with infection/sepsis, medication nonadherence respiratory failure, pulmonary embolism, or arrhythmias. The primary focus of therapy in the ICU setting consists of maintaining or improving pulmonary pressures, optimizing right ventricular (RV) function and hemodynamics, providing enhanced awareness, continuing chronic therapies, and managing the underlying cause of ICU admission. Because of the complexity of PAH treatment and the difficulties with managing this disease in the ICU setting, it is important that clinicians be familiar with its pathophysiology and potential complications and the medications used for treatment.

The critical care pharmacist plays a vital role as part of the interdisciplinary team, with an increasing number of patients being admitted to the ICU on chronic PAH treatments. With the recent approval of several pharmacologic modalities for treating PAH, the pharmacist can ascertain patient-specific adverse effects, guide prescribers on the complexity of the pharmacokinetics/pharmacodynamics for each agent, and be a stakeholder for patient education on the intravenous, inhalation, subcutaneous, and oral therapies. The purpose of this chapter is to clarify the classification of PAH versus that of PH, describe tools used for diagnosis and monitoring, and detail pharmaco-therapy options with a focus on treatment in the ICU.

---

**EPIDEMIOLOGY**

Before the advent of new therapies for PAH treatment, the median survival for this disease entity was very poor. Older data from the Patient Registry for Primary Pulmonary Hypertension also indicated poor survival for patients with the diagnosis of primary PH, with a median survival of 2.8 years (95% confidence interval, 1.9–3.7 years). Newer PAH registries indicate better survival rates than previously, but
ultimately, not an overly improved prognosis, despite the newer agents and combination treatment options currently available. The most recent Registry to Evaluate Early- and Long-term Pulmonary Arterial Hypertension Disease Management in the United States (REVEAL registry) showed an improvement in survival after 1 year, an older patient population (mean age of 53 years), a higher proportion of women (1.7:1), and a higher proportion of blacks (4.3:1).

Pulmonary hypertension is more prevalent than PAH because the most common cause of PH in the United States is left heart failure. Pulmonary arterial hypertension is a rarer entity, but if left untreated, it has a high mortality rate leading to RV failure and death. Overall, PAH tends to affect younger women more than males. Retrospective studies show that in-hospital mortality is higher in critically ill patients with PAH admitted to the ICU, ranging from 9% overall to 17% in patients with RV failure.

### PATHOPHYSIOLOGY

The targeted proven therapies for treatment of PAH have centered on three major pathways: the prostacyclin pathway, the endothelial pathway, and the nitric oxide pathway (Figure 30.1). In the prostacyclin pathway, endothelial cells form arachidonic acid that produces endogenous prostacyclin (prostaglandin I2 or PGI2). Prostaglandin I2 has many effects, including antithrombotic, anti-inflammatory, and vasodilatory effects. Epoprostenol, the first prostacyclin analog developed for PAH therapy, is the gold standard for treatment to which other therapies are benchmarked.

Another pathway contributing to PAH involves the endothelial pathway. Endothelin receptors are located on pulmonary artery smooth muscle cells and are divided into endothelin type A (ETA) and endothelin type B (ETB). Endothelin type A receptors have a higher affinity for endothelin-1, and activation leads to vasoconstriction and proliferation of vascular smooth muscle. Endothelin type B receptors can also produce these effects, but they indirectly produce vasodilation by PGI2 and nitric oxide release from endothelial cells. The
vasoconstrictive and smooth muscle effects of endothelin-1 negatively affect vessel tone and fibroblast activation. Endothelin-1 is the one subtype of naturally occurring peptides that might have the most significant impact on lung vascular remodeling.\textsuperscript{10,11}

The nitric oxide and cyclic guanosine monophosphate (cGMP) pathways are intertwined and center on nitric oxide being produced from l-arginine. Cyclic GMP and soluble guanylate cyclase (sGC) have smooth muscle relaxing effects, thought to be a result of inhibiting phosphodiesterase type 5 (PDE-5) or activating sGC, which keeps smooth muscle relaxed and averts the vasoconstrictor and platelet activation seen in PAH. Nitric oxide may independently have a positive effect on relaxation of smooth muscle.\textsuperscript{12} Nitric oxide and cGMP are key secondary targets for patient therapy.

The dysfunction and pathways described previously combine to result in intimal hyperplasia, medial thickening, and advanced remodeling and fibrosis. This, together with inflammatory and progenitor cells, has been postulated to contribute to the remodeling process of pulmonary vasculature. This progressive increase in pulmonary vascular resistance (PVR) creates an increased RV afterload and right heart failure.\textsuperscript{9} The platelet dys-function and thrombotic mechanisms are also a hallmark when describing PAH. Many vasoconstrictive substances have been implicated as a cause: von Willebrand factor, plasminogen activator inhibitor type 1, thromboxane A\textsubscript{2}, platelet-derived growth factor, transforming growth factor $\beta$, and endothelial growth factor.\textsuperscript{9,13,14} Promising advances in the genetic, molecular, and cellular mechanisms of PAH have led to novel targets as potential drug therapies.
Figure 30.1 Established vasomotor pathways targeted by current and emerging therapies in pulmonary arterial hypertension.\textsuperscript{a}

\textsuperscript{a}The three major pathways (ET-1, nitric oxide, and prostacyclin) involved in the regulation of pulmonary vasomotor tone are shown. These pathways represent the targets of all currently approved PAH therapies. Endothelial dysfunction results in decreased production of endogenous vasodilatory mediators (nitric oxide and prostacyclin) and the up-regulation of ET-1, which promotes vasoconstriction and smooth muscle cell proliferation. The ET-1 pathway can be blocked by either selective or nonselective ET-1 receptor antagonists; the nitric oxide pathway can be manipulated by direct administration of exogenous nitric oxide, inhibition of PDE-5, or stimulation of sGC; and the prostacyclin pathway can be enhanced by the administration of prostanoid analogs or non-prostanoid IP receptor agonists.

ET = endothelin; ETA = endothelin type A; IP = prostaglandin I\textsubscript{2}; NO = nitric oxide; PDE – 
Data analyses for the past 20 years link familial PAH in 80%–85% of families with a PAH family history to a gene coding bone morphogenetic protein receptor type 2 (BMPR2). The BMPR2 mutations have shown a high risk of PAH development, and the importance of this BMPR2 pathway to vascular remodeling is a focus of current research.\(^9\) Additional genetic components related to PAH include mutations to activating A receptor type II–like kinase 1 (ALK1), endoglin (ENG), and SMAD family member 9 (SMAD9) genes.\(^{15}\) Further research in this area may lead to the next generation of targets for PAH pharmacologic therapies.

**CLASSIFICATION**

Various iterations in the classification of PH have evolved from 1998 to 2015, with the most recent consensus being reached at the 5th World Symposium in Nice, France. This symposium established a
categorical clinical classification of PH according to similar hemodynamic characteristics and similar pathological findings in order to standardize management. This resulted in five groups of PH disorders (Table 30.1): group 1 (PAH), group 2 (PH caused by left heart disease), group 3 (PH caused by chronic lung disease, hypoxia, or both), group 4 (chronic thromboembolic PH), and group 5 (PH caused by unclear multifactorial mechanisms). Apart from the PH group classifications, patients can be categorized into four World Health Organization (WHO) functional classes according to their functional status and symptoms, adapted from the New York Heart Association (NYHA) classification system (Table 30.2).

The advantage for a standardized PH classification schematic is that clinicians and researchers can use similar terminology when making diagnoses and treating patients. In addition, the U.S. Food and Drug Administration (FDA) and the European Medicines Agency can do the same for new product labeling.

Pharmacists can play an important role in determining the classification of PH by obtaining a thorough medication history (including herbal supplements and over-the-counter products). Identifying definite, likely, or possible risk factors from patients with PAH who have been on medications or other toxins is key to the class 1 diagnosis. Agents linked with a definite cause of PAH include aminorex, fenfluramine, dexfenfluramine, toxic rapeseed oil, benfluorex, and SSRIs (selective serotonin reuptake inhibitors) taken during pregnancy after 20 weeks’ gestation. Agents identified as likely contributing to PAH include amphetamines, L-tryptophan, methamphetamines, and dasatinib. Agents possibly linked to PAH include cocaine, phenylpropanolamine, St. John’s wort, various chemotherapeutic agents, interferon α and β, and amphetamine-like drugs.

**DIAGNOSIS**

**Medical History**

Obtaining a personalized medical history from either the patient or the family member is key to eliciting drug or toxin exposure, familial history of PAH, and disease states contributory to PAH, which could entail connective tissue disorders (e.g., scleroderma), HIV, portal hypertension, congenital heart disease, or schistosomiasis.\(^5\)

**Physical Examination**

Patients in the ICU with PAH may present with signs and symptoms of RV failure, the most common of which are lower extremity edema, dyspnea on exertion, and angina. Patients who are syncopal have a worsening prognosis because this may reflect a low cardiac output state. Clinicians monitor for various cardiac abnormalities such as an
accentuated second heart sound, a tricuspid regurgitation, or a systolic murmur. These symptoms, in whole or in part, occur at rest and may indicate a patient with advanced PAH.\textsuperscript{5}

**Blood Tests and Immunology**

Routine blood tests comprising basic metabolic profiles, hematology, and thyroid function tests should be obtained for patients admitted to the ICU. Workup of thrombotic abnormalities includes obtaining antiphospholipid antibodies, lupus anticoagulant, and anticardiolipin antibodies. If liver involvement is suspected, liver function tests and hepatitis serologies should be obtained, together with HIV testing.\textsuperscript{2} There is some debate regarding the role of obtaining circulating biomarkers such as brain natriuretic peptide (BNP) concentrations or troponins and what they mean prognostically.\textsuperscript{2} It has been suggested that with various therapy goals in mind, achieving the lowest possible or personal best BNP or N-terminal pro–B-type natriuretic peptide (NT-proBNP) is appropriate.\textsuperscript{19}

**Chest Radiographs**

Chest radiographs are a routine part of the workup for PAH. In most patients presenting with idiopathic PAH, the chest radiograph is abnormal. “Pruning” or loss of the peripheral blood vessels is described. Right ventricular hypertrophy or dilation cannot easily be distinguished on a chest radiograph.\textsuperscript{5}

**Electrocardiogram**

Electrocardiogram (ECG), also part of the diagnostic algorithm for PAH, is used to assess RV hypertrophy and strain, as well as right atrial dilation. The ECG has a sensitivity of 55% and a specificity of 70% as a screening tool for patients with PH. Atrial arrhythmias (e.g., atrial fibrillation or flutter) are common in patients with a diagnosis of advanced PAH.\textsuperscript{5}
Echocardiography

The significance of echocardiography is that it can provide the clinician with a rough estimate of right heart size (including the RV and atrium), RV function, and possible PAH. Various equations can measure pulmonary artery systolic pressures. Although not always accurate, pulmonary artery systolic pressure can be elevated in disease states such as cirrhosis, hyperthyroidism, heart failure, kidney disease, and increased blood pressure.\textsuperscript{20} Transthoracic echocardiography serves as the most important noninvasive tool to assess PH in both ICU and non-ICU settings.\textsuperscript{21}

Pulmonary Function Tests

Making the diagnosis of PAH in critically ill patients with the aid of pulmonary function tests is often not a practical option, but if feasible, it may help identify interstitial lung disease or chronic obstructive pulmonary disease. The diffusing capacity for carbon monoxide is about 60\textendash80\% of predicted in patients with idiopathic PAH.\textsuperscript{5} The degree of hypoxemia in patients with PAH centers on ventilation-perfusion mismatch, with decreased mixed venous oxygen saturation (Svo\textsubscript{2}) values stemming from low output cardiac states.

Exercise Testing

The 6-minute walk test is a common end point marker in efficacy trials for PAH therapies.\textsuperscript{5} The 6-minute walk test is a practical simple test that requires a 100-ft hallway but no exercise equipment or advanced training for technicians.\textsuperscript{22} This test has been correlated with workload, heart rate, oxygen saturation, and dyspnea response. Cardiopulmonary testing (with an upright bicycle or treadmill) is used to grade PH severity in the outpatient setting. Treadmill testing is also an option in the ambulatory workup of PH, but it may not be an appropriate testing determination of PH in the hospital inpatient setting.\textsuperscript{21} These tests are not only used for diagnosis but also to assess disease progression.
Cardiac Catheterization—RHC

The gold standard for diagnosing and classifying severity of PAH is an RHC, with or without concomitant vasore-activity testing. Key parameters that are elicited through an RHC include right atrial pressure, pulmonary capillary wedge pressures, and RV pressure. A pulmonary capillary wedge pressure greater than 15 mm Hg excludes the diagnosis of PAH, whereas an mPAP of 25 mm Hg or greater at rest defines PAH. The gold standard for cardiac output measurement is the direct Fick method (which directly measures oxygen uptake); however, the indirect Fick method (which estimates oxygen values from tables) is not reliable. After RHC is performed and a diagnosis of PAH is made, vasoreactivity testing can be done to see whether patients are classified as either responders or nonresponders to determine whether they are candidates for calcium channel blocker (CCB) therapy.5

Vasoreactivity Challenge

The three main agents for acute vasodilator challenges are intravenous epoprostenol, intravenous adenosine, and inhaled nitric oxide. A positive acute response is defined as a reduction in mPAP of 10 mm Hg or greater to an absolute value of mPAP of 40 mm Hg or less with an increased or unchanged cardiac output (class I, level of evidence C).2

Patients admitted to the ICU are often in a decompensated state of RV failure whereby pharmacologic treatments must be titrated to improve RV function and ameliorate adverse effects (e.g., dyspnea or exercise intolerance). Patients may also be admitted for the vasodilator challenge, which may elicit better symptomatic and prognostic information. Patients classified as being in an unstable and deteriorating state have worsening WHO functional class, a poor 6-minute walk of less than 300 m, a peak VO$_2$ of less than 12 mL/minute/kg, rising BNP/NT-proBNP plasma concentrations, evidence of pericar-dial effusion, tricuspid annular planar systolic excursion less than 1.5 cm, right atrial pressure greater than 15 mm Hg, or a cardiac
index of 2.0 L/minute/m² or less. The agents and doses used for pulmonary vasoreactivity testing are intravenous epoprostenol (2–12 ng/kg/minute for 10 minutes), intravenous adenosine (50–350 mcg/kg/minute for 2 minutes), or inhaled nitric oxide (10–20 ppm for 5 minutes).

**TREATMENT**

**Calcium Channel Blockers**

Calcium channel blockers decrease calcium influx into the smooth muscle cells of the arterial wall and the myocardial cells by inhibiting L-type voltage-dependent sodium channels. This also represents a possible mechanism of PAH development. The concept of CCB responders versus non-responders is relevant when considering CCB as an agent to treat patients with PAH because about 5% of patients will benefit from CCB treatment long term. Two studies have shown that CCB may be useful in patients with PAH. Rich and colleagues studied CCB therapy in 47 patients with PAH. These authors found a 20% reduction in mPAP and PVR (with nifedipine and diltiazem in 72% of patients), with 15 patients (32%) defined as pressure responders (significant improvement in mPAP and PVR index). In another study by the same lead author, 17 of 64 patients (27%) had a 20% reduction in mPAP and PVR when treated with nifedipine 20 mg or diltiazem 60 mg, with a 94% survival at 5 years (compared with 55% in patients who did not respond to therapy)

Advanced therapies with acute vasoactive agents such as adenosine, epoprostenol, and nitric oxide have replaced CCB as the preferred agents in clinical trials. This is primarily due to the significant adverse effects of the CCBs, which include negative inotropy (diltiazem and verapamil), hypotension (seen with all agents with escalating doses from CCB trials), edema, nausea, headache, and acute hospitalization.

Overall, CCB efficacy is limited in patients with PAH, and these agents are contraindicated in most patients given the presence of decompensated right/left heart failure or bradycardia.
CCBs have been relegated to possible last-line therapies, but they are a viable option for patients who may not respond to other therapies.

**Implications for the Critical Care Practitioner**

Although not widely recommended, CCB agents may be used in the early stages of PAH because of their availability and ease of administration. Patients should be closely monitored for changes in blood pressure and heart rate as well as other potential adverse effects. Critical care monitoring flowsheets and medication administration records should be closely monitored to determine the accuracy and efficacy of dosing and the potential need for alterations in therapy.

**Epoprostenol Analogues**

The mainstay of PAH therapy in the critically ill patient has traditionally been epoprostenol. Epoprostenol is a prostacyclin PGI$_2$ analog with unique pharmacologic properties, including direct vasodilation of the pulmonary vasculature and platelet aggregation inhibition. Epoprostenol has shown symptomatic and hemodynamic improvements in patients with severe primary PH, survival benefits longer term in patients with NYHA function class III or IV, and mortality benefits in subsets of patients with PH caused by scleroderma.\textsuperscript{28,29} In a 12-week, prospective, randomized trial of 81 patients with severe primary PH (NYHA functional class III or IV), 41 patients treated with intravenous epoprostenol at a mean dose of approximately 9 ng/kg/minute showed exercise capacity improvements (6-minute walk test) and hemodynamic improvements (pulmonary artery pressures, PVR) compared with conventional therapies. The most noteworthy finding showed improved survival at 12 weeks in the epoprostenol group, with eight patients dying in the conventional group ($p = 0.003$) after adjustment of variables.\textsuperscript{28} Newer trials have shown similar results in both hemodynamic and survival improvement with epoprostenol.

Epoprostenol is FDA labeled for the treatment of PAH in WHO group
1 patients to improve exercise capacity. The recommended starting dose is 2 ng/kg/minute intravenously, and the dose is slowly titrated in increments of 0.5–2 ng/kg/minute every 15 minutes to a maximum tolerated dose. The most common adverse effects are nausea, vomiting, jaw pain, headache, flushing, erythema, anxiety, musculoskeletal aches/pain, and photosensitivity. Epoprostenol can also be administered by the inhalational route; however, this has not been well studied in PAH. A typical dosing strategy is to administer 50–85 mcg/kg/minute by nebulizer and then taper to the maximum effect. Another strategy is to nebulize at a fixed concentration of 10–20 mcg/mL at a rate of 0.2–0.3 mL/minute.

**Implications for the Critical Care Practitioner**

Epoprostenol requires close monitoring because of the effects on decreasing blood pressure, heart rate, increased risk of bleeding, short half-life (4–5 minutes), and unstable nature (specifically the Flolan product). Administration of epoprostenol is through a central line with a 0.22-micron filter; however, a peripheral line may be used on a short-term basis until central access can be established. There are infectious risks from pulmonary artery catheterization, as well as central and peripheral line infections, with the most common pathogens being *Staphylococcus aureus* and *Micrococcus* spp. The pharmacist should have a good understanding of the different infusion pumps (for home use), priming rates and volumes needed, typical dosage titrations required for acute therapy in the ICU, risks associated with interrupted PGI₂ therapy, adverse effects and their potential treatments to optimize titration, compounding, distributing process for timely administration, diluents required for admixture (sterile diluent for Flolan and either 0.9% sodium chloride or sterile water for Veletri), and strategies for transitioning to alternative therapy such as treprostinil.

There are critical elements about epoprostenol management that place the pharmacist at the forefront of care. These center on the use of correct and constant dosing weights, expertise of shelf lives of the various products used, and practical coordination of backup
cartridges/intravenous bags if the patient is in the ICU for greater than 24 hours. Patient dosing weights need to be based on original weights for the patient (and rates that patients have been titrated to in the outpatient setting) and may need to be verified by home infusion nurses/pharmacists or other providers. Errors can occur with nanogram per kilogram per minute conversions to microgram per kilogram per minute conversions by hospital-based pumps, so the patient-pharmacist interaction and medication reconciliation on admission is paramount. Backup cartridges (if patients are stable to mix their own infusions) or infusion bags need to be stored appropriately and made available to the nursing units, which requires interdisciplinary collaboration. This change can be seen with the newer Veletri agent and the need for every 24- to 72-hour changes, instead of more frequent 8-hour switches with the older product. Finally, titration of the agent epoprostenol needs to be managed by experienced physicians because hemodynamic instability can occur if lines are primed, agents are abruptly discontinued, or the patient’s baseline condition worsens.

Transitioning from intravenous epoprostenol to oral or subcutaneous dosage forms of other classes has been described in case reports in the literature with success, with recommendations not specific regarding whether these can be done in an acute critical care situation. Other transitions from subcutaneous to intravenous to inhalational have been described.

Conversion from epoprostenol to treprostinil is accomplished by initiating treprostinil while simultaneously decreasing epoprostenol. The treprostinil package insert recommends a seven-step process (Table 30.3).

Treprostinil

Treprostinil is a tricyclic benzidine analog of epoprostenol that has a comparatively longer half-life (4–4.5 hours) and is more stable in solution than epoprostenol. Treprostinil is FDA labeled to improve exercise capacity in WHO group 1 patients with PAH. Treprostinil has several routes of administration, including intravenous, subcutaneous, inhalational, and oral.
The efficacy of this agent has been shown in several clinical trials. A double-blind, randomized trial of the subcutaneous infusion was compared with placebo in 470 patients with PAH. Treprostinil dosed at 1.25 ng/kg/minute titrated to effect to a maximum of 22.5 ng/kg/minute over 12 weeks resulted in improved 6-minute walk distance, Borg dyspnea score, pulmonary hemodynamics, and quality of life. The TRIUMPH-1 study was a randomized controlled trial of the addition of inhaled treprostinil or placebo to oral therapy with bosentan or sildenafil in 235 patients with NYHA class III or IV PAH. Treprostinil was initiated at a dose of three inhalations four times daily titrated to a maximum of nine inhalations four times daily. Patients in the treprostinil group had a mean increase of 19 m in the 6-minute walk distance and increased quality of life. Two randomized controlled trials (FREEDOM C and FREEDOM C2) investigated the oral dosage form of treprostinil to bosentan or sildenafil in patients with PAH. The FREEDOM C trial randomized 350 patients to 1 mg of oral treprostinil twice daily to a maximum of 16 mg twice daily or matching placebo. The FREEDOM C2 trial randomized 310 patients to 0.25 mg of oral treprostinil twice daily (mean dose 3.1 mg twice daily) or matching placebo. Neither trial showed a difference in the primary outcome of the 6-minute walk distance. A third trial of monotherapy with oral treprostinil at a starting dose of 0.25–1 mg twice daily to a maximum dose of 12 mg twice daily or placebo showed a difference in 6-minute walk distance and the combined end point of 6-minute walk distance and Borg dyspnea score.

</table>

Dosing of treprostinil varies by the route of administration. The initial dosing of intravenous treprostinil (Remodulin) is typically 1.25 ng/kg/minute, but this should be reduced to 0.625 ng/kg/minute in severe hepatic insufficiency. The infusion rate should be increased in increments of 1.25 ng/kg/minute per week for the first 4 weeks of treatment and then 2.5 ng/kg/minute per week for the remaining duration of infusion to clinical response. In the ICU setting, the dosing titration may be more rapid, with a starting dose of 1–3 mg/kg/minute, gradually increased by 1–2 ng/kg/minute two or three times weekly. The dosing of the inhalational form (Tyvaso) is rarely initiated in the ICU because of the difficulties with the required inhalation system. In these cases, the patient should be transitioned to intravenous therapy. The inhalational form of treprostinil in the outpatient setting is typically initiated as three inhalations four times daily spaced at least 4 hours apart and is increased by three inhalations every 1–2 weeks to a maximum of nine inhalations four times daily.

Oral treprostinil therapy may also be initiated in the outpatient setting. The dosing of Orenitram is 0.25 mg twice daily or 0.125 mg three times daily administered with food. The dose is increased in increments of 0.25 or 0.5 mg twice daily or 0.125 mg three times daily every 3–4 days to achieve optimal clinical response. Oral treprostinil should be avoided in severe hepatic insufficiency and used with caution.
because tablets may lodge in diverticuli. The most common adverse effects with treprostinil are hypotension, jaw pain, chest pain, flushing, cough, headache, dizziness, throat irritation, nausea, and diarrhea. If administered in the ICU setting, the extended-release tablets cannot be split, crushed, or chewed.

**Implications for the Critical Care Practitioner**

Diluents required for the intravenous treprostinil admixture include the sterile diluent, 0.9% sodium chloride, or sterile water. Subcutaneous administration may lead to infusion-site reactions, which occur with a prevalence of about 10%. This has prompted some patients to be transitioned to the intravenous or inhalation route. Strategies to reduce these reactions include avoiding sensitive areas, relocating to a new infusion site (abdomen, thighs, posterior upper arms, etc.), and using topical agents (ice, topical agents such as lidocaine, corticosteroids, antihistamines, or calcineurin inhibitors), and oral nonsteroidal agents, anti-histamines, or GABA [γ-aminobutyric acid] analogs.  

The conversion for patients being switched from intravenous treprostinil to intravenous epoprostenol is approximately 1.25:1, respectively. Dosing of the subcutaneous formulation requires re-titration if the infusion is stopped for more than 4–6 hours, and the oral formulation requires re-titration if more than two consecutive doses are missed. The adverse effect profile of treprostinil is different from that of epoprostenol. With the treprostinil half-life being 4 hours versus 4–6 minutes with epoprostenol, this offers the theoretical advantage of not causing the major rapid pulmonary vasoconstriction and emergency situations that would be seen in sudden discontinuation.

**Iloprost**

Iloprost is another example of a prostacyclin analog that is administered as an inhalation, but it can also be given by the intravenous route (although not available in the United States). Iloprost is FDA labeled for the treatment of PAH (WHO group 1) to improve a composite end point consisting of exercise tolerance, symptoms (NYHA
class), and lack of deterioration. Data behind the efficacy of inhaled iloprost centers on the Aerosolized Iloprost Randomized Study (AIR) trial, which randomized patients to receive up to 30 mcg per day (2.5 or 5 mcg inhaled six to nine times per day) or placebo. Patients who received iloprost showed improvements in 6-minute walk distance, symptom improvement (NYHA class), decreased PVR, less dyspnea, and improved quality of life.

Iloprost is initially dosed at 2.5 mcg administered as six to nine inhalations per day at least 2 hours apart by the I-neb AAD system. If the 2.5-mcg dose is well tolerated, the dose can be increased to 5 mcg. Patients with severe hepatic impairment (Child-Pugh class B or C) should have the dosing interval increased to 3–4 hours. Renal dosing adjustments are not required. The adverse effect profile of iloprost is similar to that of epoprostenol and treprostinil, with the most common adverse effects of hypotension, bronchospasm, cough, jaw pain, and headache. There are no significant drug interactions; however, concurrent use with antihypertensive agents, anticoagulants, and platelet inhibitors should be closely monitored.

**Implications for the Critical Care Practitioner**

Doses should be reduced (and may need to be avoided) if the systolic blood pressure (SBP) is less than 85 mm Hg or if pulmonary edema develops. There are several limitations to administration of inhaled iloprost, including the feasibility of inhalations administered six to nine times per day, inability to mix with other medications, and inability to administer if a patient requires mechanical ventilation. Patients on mechanical ventilation may receive iloprost by ultrasonic nebulizer; however, this strategy has not been well studied. Therefore, patients admitted to the ICU may need conversion to other agents or discontinuation of therapy if unresponsive to self-inhalation techniques.

**Endothelin Receptor Antagonists**

Endothelin-1 causes vasoconstriction and cell proliferation through
activation of the ETA and ETB receptors on smooth muscle cells. Endothelin type A mediates vasoconstriction, whereas ETB mediates vasodilation through release of nitric oxide. The mechanism of action for the endothelin receptor antagonists is selective ETA antagonism with minimal effect on ETB.

Several clinical trials have shown the efficacy of the endothelin receptor antagonists. The BREATHE-1 trial was a double-blind, placebo-controlled, multicenter study of bosentan in 213 patients with PAH. Patients were randomized to one of three groups: bosentan 62.5 mg twice daily increased to 125 mg after 4 weeks of treatment (n = 74), bosentan 62.5 mg twice daily increased to 250 mg after 4 weeks of treatment (n = 70), or placebo (n = 69). The primary outcome of 6-minute walking distance was increased overall by 44 m in bosentan-treated patients (27 m in the bosentan 125-mg group and 46 m in the bosentan 250-mg group), which was a statistically significant difference compared with a decrease of 8 m in the placebo group. Patients treated with bosentan also showed improvements in secondary clinical end points monitored, including Borg dyspnea score, change in WHO functional class, and clinical worsening defined as the sum of death, hospitalization for PAH, discontinuation of therapy for PAH, and need for epoprostenol.

The SERAPHIN trial was a phase III, multicenter, double-blind, randomized, placebo-controlled, event-driven study of macitentan in 742 patients with PAH. Patients were randomly assigned to one of three treatment groups: macitentan 3 mg daily, macitentan 10 mg daily, or placebo. The primary outcome of the time from the initiation of treatment to the first occurrence of a composite end point of death, atrial septostomy, lung transplantation, initiation of treatment with intravenous or subcutaneous prostanoids, or worsening of PAH was seen in 31.4% of patients in the macitentan 10-mg group, 38% of patients in the macitentan 3-mg group, and 46.4% of patients in the placebo group.

The ARIES-1 and ARIES-2 trials were concurrent, double-blind, placebo-controlled trials that randomized patients with PAH to placebo or ambrisentan 5 or 10 mg (ARIES-1) or placebo or ambrisentan 2.5 or
5 mg (ARIES-2).  

All ambrisentan groups showed an increase in the primary outcome of 6-minute walk test distance compared with placebo (ARIES-1: 31 m and 51 m for ambrisentan 5 mg and 10 mg, respectively; ARIES-2: 32 m and 59 m for ambrisentan 2.5 mg and 5 mg, respectively).

All three of the currently available endothelin receptor antagonists are FDA labeled for the treatment of PAH in WHO group 1 patients to improve exercise ability and to decrease clinical worsening.  

Ambrisentan is initiated at a dose of 5 mg daily, which can be increased to 10 mg daily if tolerated. Bosentan is initiated at 62.5 mg twice daily, which can be increased to 125 mg twice daily. Macitentan is dosed at 10 mg daily (higher doses are not recommended). Renal adjustment is not needed for bosentan or macitentan; however, ambrisentan is not recommended for patients with a creatinine clearance (CrCl) less than 20 mL/minute/1.73 m$^2$. All three agents should be avoided in moderate to severe hepatic impairment.

The most common adverse effects with the endothelin receptor antagonists are anemia, nasal congestion, sinusitis, fluid retention, headache, bronchitis, and urinary tract infections. The major drug interactions vary between agents; however, all three agents have increases in serum concentrations when administered with strong cytochrome P450 (CYP) 3A4 (and CYP2C9 with bosentan) inhibitors and decreases in serum concentrations when administered with strong CYP3A4 inducers. All three agents are pregnancy category X and should be avoided in females who are or may become pregnant.

**Implications for the Critical Care Practitioner**

The endothelin receptor antagonists are associated with an increase in peripheral and pulmonary edema, increased bleeding risks, and increases in liver function tests; patients should be closely monitored for signs and symptoms of these potentially serious effects. Decreases in hemoglobin concentrations of more than 0.8 mg/dL are considered significant and warrant further investigation to determine the causality. Medications in this class should not be crushed; however, bosentan
tablets can be split or dissolved in water. If oral or tube administration is not possible, conversion to an intravenous alternative (typically epoprostenol) may be required. With oral agents in this class, it is rare to initiate them in the ICU. Typically, the more critical treatment decision is when to discontinue or hold endothelin receptor antagonists when a patient presents with significant hypotension.31

**PDE-5 Inhibitors**

Nitric oxide induces the formation of intracellular cGMP, which leads to relaxation of the pulmonary vascular smooth muscle and dilation of the pulmonary arterioles.54 The iso-enzyme that is primarily responsible for the breakdown of cGMP is PDE-5. Inhibitors of PDE-5 increase cGMP concentrations and allow for prolonged action of cGMP. Clinical studies with both sildenafil and tadalafil have shown the efficacy of the PDE-5 inhibitors in reducing clinical worsening, improving 6-minute walk test, and improving quality of life, but with no reduction in mortality.55-57

Sildenafil (Revatio) is FDA labeled for the treatment of PAH in WHO group 1 adults to improve exercise ability and delay clinical worsening.58 The oral dose is 5 or 20 mg three times daily, spaced at least 4–6 hours apart. The intravenous dose is 2.5 or 10 mg three times daily administered as a bolus. No dose adjustments are recommended for renal or hepatic impairment. The Viagra formulation of sildenafil is not FDA labeled for use in PAH, but several studies and case series have shown an improvement in pulmonary hemodynamics at doses of 25–100 mg per day.56,59

Tadalafil is FDA labeled for the treatment of PAH in WHO group 1 adults to improve exercise ability.60 The dose is 40 mg once daily, and doses should not be divided. For patients with mild to moderate renal impairment (CrCl 31–80 mL/minute/1.73 m²) or hepatic impairment, the dose should be decreased to 20 mg daily. Use of tadalafil should be avoided for severe renal impairment (CrCl less than 30 mL/minute/1.73 m²) or hepatic cirrhosis.

The most common adverse effects associated with the PDE-5 inhibitors are epistaxis, headache, flushing, erythema, dyspepsia,
rhinitis, hypotension, priapism, and visual or hearing loss.\textsuperscript{58,60} Significant drug interactions include the CYP3A4 inhibitors, amlodipine, α-receptor blocking agents, and organic nitrates. For patients who may require nitrate administration for chest pain, it is recommended to avoid these agents for at least 24–48 hours after the last dose. Blood pressure should be closely monitored in these patients.

**Implications for the Critical Care Practitioner**

Phosphodiesterase type 5 inhibitors may cause hypotension and a resultant increase in heart rate; patients should be closely monitored for signs and symptoms of these potentially serious effects. Sildenafil is available as an oral suspension; however, tablets of all PDE-5 inhibitors can be crushed for feeding tube administration. Others forms of sildenafil (e.g., Viagra) may be used for PAH if needed due to institutional formulary restrictions.

**sGC Stimulator**

Riociguat is a novel agent for the treatment of PAH. The mechanism of action is through stimulation of sGC and increased binding to nitric oxide to sGC, leading to an increase in synthesis of cGMP by the nitric oxide–sGC–cGMP pathway.\textsuperscript{61} The beneficial effects of cGMP in PAH include vasodilation, inhibition of smooth cell proliferation, prevention of fibrosis, and antithrombotic and anti-inflammatory effects.\textsuperscript{61}

Riociguat has shown efficacy in two major trials: PATENT-1 and CHEST-1. The PATENT-1 trial was a phase III randomized controlled study of 443 patients with PAH.\textsuperscript{62} Patients with symptomatic PAH who received riociguat 2.5 mg three times daily showed a 30-m increase their 6-minute walk test from baseline compared with a decrease of 6 m in the placebo group. The CHEST-1 trial was a phase III, multicenter, randomized, double-blind, placebo-controlled study of 261 patients with inoperable chronic thromboembolic PH.\textsuperscript{63} Patients who received riociguat 1 mg three times daily showed a 39-m increase their 6-minute walk test from baseline compared with a decrease of 6 m in
the placebo group.

Riociguat is FDA labeled for the treatment of WHO group 1 PAH to improve exercise capacity, improve WHO functional class, and delay clinical worsening. It is also FDA labeled for persistent or recurrent chronic thromboembolic PH (WHO group 4) after surgical treatment or inoperable chronic thromboembolic PH to improve exercise capacity and WHO functional class. The starting dose is 1 mg three times daily, but this may be reduced to 0.5 mg three times a day for patients with low blood pressure at initiation, or those who develop low blood pressure after initiation. Doses are titrated in increments of 0.5 mg to a maximum of 2.5 mg three times daily. No dosage adjustments are required for renal or hepatic insufficiency, but use is not recommended for a CrCl less than 15 mL/minute/1.73 m², hemodialysis, or severe hepatic impairment (Child-Pugh class C). Riociguat is contraindicated in pregnancy (pregnancy category X).

The most common adverse effects of riociguat are headache, dyspepsia/gastritis, dizziness, nausea, diarrhea, hypotension, vomiting, anemia, gastroesophageal reflux, and constipation. Significant drug interactions include azole antifungals, protease inhibitors, nitrates, and PDE-5 inhibitors, all of which may lead to increased hypotensive effects requiring riociguat dose reductions.

**Implications for the Critical Care Practitioner**

Riociguat may increase the risk of bleeding, hypotension, and pulmonary edema; patients should be closely monitored for signs and symptoms of these potentially serious effects. There are few data regarding the ability to split or crush the tablet, but the manufacturer recommends to avoid this because of teratogenic concerns. If doses are held for more than 3 consecutive days, patients will require retitration to their chronic dosage schedule. For patients with a current history of smoking, higher doses may be required in the ICU setting because of an increase in serum concentrations secondary to abrupt discontinuation of smoking (50%–60% serum concentration reduction in smokers).
Supportive Therapies

In addition to the vasodilators, there are several adjunctive therapies that may be beneficial in PAH therapy and are recommended in the most recent guidelines. As discussed previously, patients with PAH are at an increased risk of thromboembolism and may benefit from anticoagulation. Use of anticoagulants in this setting is somewhat controversial; however, warfarin is recommended, titrated to an INR (international normalized ratio) of 1.5–2.5 if no bleeding contraindications exist. Diuretics are recommended in patients with PAH with signs of RV failure and fluid retention; however, no specific recommendations are made regarding choice of agents. Digoxin may improve cardiac index (short-term effect), but it is most commonly used for patients with PAH who develop atrial tachycardia in order to slow the ventricular rate. These strategies may be used in the ICU setting unless contraindicated due to the underlying critical illness.

Treatment of the Critically Ill Patient with PAH

Pulmonary arterial hypertension in itself can cause the acute RV decompensation. This is of particularly concern when patients are admitted to the ICU on several pharmacologic therapies. The RV adapts poorly to sudden increases in afterload, and this can result in decreased contractility and hemodynamic collapse. Right ventricular dysfunction can result from excess RV afterload, inadequate RV preload, decreased RV contractility, or altered systemic vasodilation. In the ICU setting, additional triggers such as sepsis, trauma, anemia, pulmonary embolism, medication nonadherence, interruption of chronic therapy, and arrhythmias can quickly overwhelm the effectiveness of any RV compensatory mechanisms.

Overall treatment goals are to manage fluids judiciously, reduce venous filling pressures, and normalize cardiac output (Figure 30.2). Fluid management should consist of maintaining net negative fluid balance in patients with RV failure and PAH. This may require the use of diuretic therapy or renal replacement therapies as indicated. For maintenance of blood pressure and cardiac output, various agents are
preferred. Dobutamine is a $\beta_1$-agonist that decreases right and left ventricular afterload and improves cardiac output. This agent has adverse effects related to tachyarrhythmias, which can be problematic in low cardiac output states. Another option is milrinone, a phosphodiesterase type 3 inhibitor. In addition to milrinone's inotropic properties, it acts as a pulmonary vasodilator and improves RV function and decreases PVR.\(^\text{67}\)

If vasoconstrictors are indicated due to the systemic vasodilation caused by dobutamine, then norepinephrine (predominantly an $\alpha_1$- vasoconstrictor at increasing dosages starting at 5–10 mcg/minute) is the vasopressor of choice. Other options for vasopressors include phenylephrine and vasopressin; dopamine and epinephrine are considered last-line options because of the increased potential for adverse effects. Inhalational formulations of phosphodiesterase inhibitors such as milrinone have not been studied in these patients.\(^\text{68}\)

Patients with acutely decompensated PAH require immediate stabilization to improve oxygenation, optimize preload, decrease afterload, and improve RV contractility, all while maintaining therapeutic pulmonary pressures. They also require interventions to their maintenance regimens to dose adjust for end-organ complications such as renal or hepatic dysfunction. Patients with newly diagnosed advanced PAH require centers with expertise in PH management. If further treatments are required after advance treatments and combinations are used, lung or heart-lung transplantation, or the use of bridge therapies with venovenous and venoarterial extracorporeal membrane oxygenation, may be indicated.
**Initial Patient Stabilization**
- Assess airway, breathing, and circulation
- Supplemental oxygen for SaO2 < 90%
- Central line placement
- Consider pulmonary artery catheter placement

**Optimize Preload**
Fluid management:
- Goal is to maintain slight negative balance
- IV diuretics or hemofiltration

**Decrease RV afterload**
- Inhaled nitric oxide
- Prostacyclin analogues
  - Epoprostenol IV / INH
  - Treprostinil SC / IV / INH
  - Iloprost INH / IV
- Sildenafil IV

**Measure cardiac index**

**Measure mean arterial pressure**

**Measure oxygen saturation**

**Administer inotropic agents**
- Dobutamine 5 - 10 mcg/kg/min
- Milrinone 0.375 – 1 mcg/kg/min
- Levosimendan* 0.1 mcg/kg/min
  *Not available in the US

**Administer vasopressors**
- Norepinephrine 3 - 10 mcg/min
- Phentylephrine 20 – 40 mcg/min
- Vasopressin 0.01 – 0.04 units/min

**Administer oxygen**
- Mechanical ventilation
- ECMO
Most PH centers have developed treatment algorithms for patients admitted with worsening heart failure. If patients are currently maximized on diuretics, inotropes, intravenous prostacyclins, PDE-5 inhibitors, and endothelin receptor antagonists, inhaled nitric oxide or inhaled prostaglandins (epoprostenol) can be used as last therapeutic options.

**MONITORING OF THE CRITICALLY ILL PATIENT WITH PAH**

Monitoring of the ICU patient with PAH is important for several reasons, including the evaluation of treatment strategies, potential adverse effects of therapy, and clinical worsening. Although the use of pulmonary artery catheters has declined in the ICU, these devices are important for measuring hemo-dynamic parameters in patients with PAH, including RA pressure, left atrial pressure, cardiac output, and \( Svo_2 \). Echocardiography may be useful in settings where more invasive monitoring is unavailable. Together with cardiac and pulmonary hemodynamic monitoring, patients should have their renal and hepatic function, tissue perfusion/oxygenation, neurohormonal markers, and markers of fluid balance (e.g., daily weight and fluid input and output) monitored very closely (Table 30.4).\(^6^5\) Cardiac biomarkers, such as troponin and natriuretic peptides, may also be useful given that increases in these values are associated with worsening outcomes in PAH.\(^6^8\)

**PRACTICAL CONSIDERATIONS FOR THE CRITICAL CARE PHARMACIST**
The treatment of patients with PAH in the ICU can pose a challenge, and recent data analyses point out that they constitute a complex patient population receiving high-risk medications. A national survey emphasized serious or potentially serious intravenous prostacyclin administration errors. There are four major considerations regarding the role of the pharmacist and potential areas of intervention for the critically ill patient with PAH. First, the stability of the patient is of paramount importance. Depending on overall patient status (especially RV failure, septic shock, and cardiogenic shock), intravenous, inhalational, or oral therapies may require adjustment or discontinuation. The RV adapts poorly to sudden increases in afterload, and this can result in decreased contractility and hemodynamic collapse. Right ventricular dysfunction can result from excess RV afterload, inadequate RV preload, decreased RV contractility, or altered systemic vasodilatation. In the ICU setting, additional triggers such as sepsis, trauma, anemia, pulmonary embolism, medication nonadherence, interruption of chronic therapy, and arrhythmias can quickly overwhelm the effectiveness of any RV compensatory mechanism.

Because of the short half-life of these agents, most patients should be kept on intravenous prostacyclin without interruption. This includes careful medication reconciliation, often requiring a call to the company providing the parenteral prostacyclin to confirm original dosing weight, rate of administration, and vial concentration. The next decision may involve the provision and decision to use patients’ home infusion pumps or may involve whether to convert the patient to a hospital-based pump where therapies can be prepared and supplied solely from the pharmacy department. Second, there are concerns for the oral or enteral agents with respect to how they can be administered in the mechanically ventilated patient or NPO (nothing by mouth) patient. Among the PDE-5 inhibitors and endothelin antagonists, only sildenafil has a commercially available suspension and is an intravenous alternative, with the five other agents available as tablets or capsules with limited ability to administer enterally or parenterally (Table 30.5). Inhalation treatments such as inhaled iloprost may pose a problem in
dosing frequency with a patient on either invasive or noninvasive mechanical ventilation. Of note, when these PAH medication classes were FDA labeled for use in the United States, studies assessing their safety in the critically ill ICU patient were not done. This requires clinical judgment and individualization of therapy when dosing patients with PAH. Third, practitioners need to understand and be well-versed when patients present to the ICU with infected Hickman or PICC (peripherally inserted central catheter) lines and know how to convert to other therapies with the correct priming volumes. Fourth, anticoagulation of the patient with PAH in the ICU, treatment of pregnant patients with PAH, and the decision about mechanical ventilation in the decompensated patient all require the interdisciplinary team to weigh in on these decisions.

Finally, there should be consideration of administrative oversight from an interdisciplinary perspective on keeping these patients with PAH safe when being admitted to inpatient settings. This could take the form of protocol/ guideline development as it relates to acute vasoactive trials while in the ICU, policies on the criteria of when...
patients should be transitioned from home intravenous/sub-cutaneous pumps, electronic medical record assimilation of order sets, and, finally, the integration of home-based infusion services and their roles in educating patients in the institutional setting.

LEARNING OBJECTIVES

1. Summarize the economic impact of acute asthma and COPD on the healthcare system.

2. Evaluate and compare pathophysiologic differences between asthma and COPD.

3. Identify criteria for ICU admission for acute asthma and COPD.

4. Recommend goals/treatment strategies of asthma management in critically ill patients.

5. Recommend goals/treatment strategies of COPD management in critically ill patients.

6. Explain the therapeutic approach to Asthma-COPD overlap syndrome.

ABBREVIATIONS IN THIS CHAPTER
INTRODUCTION

Acute respiratory failure secondary to asthma or chronic obstructive pulmonary disease (COPD) commonly requires frequent and prolonged admission to an intensive care unit (ICU). Although mortality has improved over time in patients with asthma, COPD is now the third leading cause of death in the United States. In addition, there has been increased awareness and focus on asthma COPD overlap syndrome (ACOS). Much of the published literature on these topics has targeted epidemiology, pathophysiology, clinical diagnosis, and outpatient and emergency department (ED) therapeutic management, with limited
focus on ICU therapeutic management. Although this chapter will briefly review the epidemiology, pathophysiology, and clinical diagnosis of these diseases, further detailed mechanisms and pathways are beyond the scope of this chapter and may be found in several exceptional texts, guidelines, and reviews. The primary focus of this chapter will be on the evidence-based approach to ICU management of asthma, COPD, and ACOS.

OVERVIEW OF ASTHMA AND COPD

Epidemiology
Asthma and COPD are significant contributors to morbidity and mortality internationally and have a considerable impact on health care costs. The overall economic impact in the United States is reportedly $56 and $49.9 billion annually for asthma and COPD, respectively.\(^1,2\)

Asthma, which tends to develop early in life, is genetically and environmentally influenced. The Centers for Disease Control and Prevention (CDC) statistics indicate that 25.7 million people in the United States are given a diagnosis of asthma, increasing steadily from 3.1% in 1980 to 8.4% of the population in 2010.\(^2\) This increase in asthma diagnosis in 2010 had a minimal impact on ED visits and hospitalizations, accounting for 1.8 million visits and 439,000 admissions, respectfully. Mortality is usually preventable, as shown by the steady decrease in CDC mortality rates despite similar hospitalizations since 2001. This is secondary to the successful reversibility of airway inflammation with early treatment.

Despite decreasing mortality, the health care impact remains substantial. One-fourth of all ED visits are secondary to asthma exacerbations, and 5%–10% reportedly require ICU admission.\(^3,4\) Childhood respiratory infections including respiratory syncytial virus and parainfluenza virus may influence the development of asthma.\(^5\) Environmental factors that influence the development of asthma include allergens, tobacco smoke, air pollution, and some occupational exposures. Risk of mortality is heightened in pediatric patients,
females, black Americans, and those with lower socioeconomic status.2

Chronic obstructive pulmonary disease has been diagnosed in about 14.2 million people nationally, varies drastically by state, and was associated with 1.5 million ED visits, 715,000 hospitalizations, and 133,965 deaths in 2009.1,6,7 It is reportedly the third leading cause of mortality, with a rate of 40.8 per 100,000 deaths in 2010, preceded by cancer and cardiovascular disease.8 Chronic obstructive pulmonary disease exacerbations resulting in hospitalizations reportedly account for 40%–75% of associated COPD health care costs.9 Upward of 20% of COPD hospitalizations may result in ICU admission.10 Smoking and age are the greatest risk factors for developing COPD, and patients with COPD typically present with several comorbidities including, but not limited to, coronary artery disease, congestive heart failure, diabetes with neuropathy, atrial fibrillation/flutter, and lung cancer.9

There is increasingly more literature regarding ACOS.11 The prevalence has been difficult to characterize because often patients with characteristics of a secondary disease were excluded from clinical trials, and in clinical trials that were inclusive, different definitions were used to characterize these patients.11–15 In trials that have investigated overlap syndrome, the prevalence of asthma in COPD cohorts ranged from 15% to 55%.11 Patients with ACOS are reportedly younger and experience a greater frequency and severity of exacerbations.13 A large multicenter population-based survey using standardized definitions to classify asthma, COPD, and overlap syndrome showed that patients with ACOS have worse general health status, increased exacerbation risk, and more hospitalizations than do those with COPD alone.15

**Pathophysiology**

Acute respiratory failure requiring ICU admission is characterized by the inability to maintain homeostasis secondary to hypercapnia and hypoxemia.16 Severe asthma and COPD exacerbations can induce
acute respiratory failure, but through different pathophysiologic pathways. Asthma is defined by the Global Initiative for Asthma (GINA) as “a heterogeneous disease, usually characterized by chronic airway inflammation.”\(^5\) It is an immunohistopathologic process mediated by cytokine release and chemokines that trigger and regulate transcription factors that induce inflammatory response.\(^5\) The immunologic findings in sudden-onset and fatal asthma differ from those in slow or late-onset asthma, such that neutrophils in bronchial epithelium are more predominant in sudden-onset compared to eosinophils in late-onset. Occupational asthma and smokers also have a predominance of neutrophils. Mast cell activation and epithelial cell injury, together with sub-basement membrane thickening, bronchial smooth muscle hypertrophy and hyperplasia, and increased mucus secretions, contribute to airway structural changes and resultant inflammation.\(^5\) These factors influence the severity of asthma according to the degree of obstruction of airflow caused by bronchial smooth muscle contraction, bronchial inflammation-associated mucosal edema, and mucus plugging.\(^{17,18}\)

In allergic asthma, the degree of cross-linking of immunoglobulin E (IgE) antibodies by allergen influences the development and severity. This type of bronchoconstriction is induced through mast cell activation and release of histamine, tryptase, cysteinyl-leukotrienes, and prostaglandin D\(_2\).\(^5,19–21\) Macrophages may further release cytokines and inflammatory mediators after allergen activation.\(^5,22\) Airway obstruction results in a decrease in forced expiratory volume in 1 second (FEV\(_1\)), which in turn leads to air trapping and increasing functional residual capacity and a decreased forced vital capacity (FVC). Thus, a decreased FEV\(_1\)/FVC ratio, with partial bronchodilator reversibility, is characteristic of asthma. Research is emerging showing inflammatory volatility, in which selective treatment based on phenotype may target improved therapeutic response. Some encouraging research efforts have been focused on leukotriene modifiers and anti-IgE, and continued investigations are under way.\(^5,23\)

Chronic obstructive pulmonary disease has been defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD)
guidelines as “a common preventable and treatable disease, characterized by airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases.” Chronic obstructive pulmonary disease typically develops later in life, is characterized by a limitation in expiratory flow and hyperinflation that is not completely reversible, and is usually confounded by several comorbidities. Chronic obstructive pulmonary disease can resemble aspects of both emphysema (alveolar damage) and chronic bronchitis (airway inflammation). The repeated exposure to noxious stimuli activates neutrophils and macrophages, which leads to airway remodeling, mucous hypersecretion, and impaired ciliary function resulting in carbon dioxide (CO₂) retention. In smokers, cytotoxic T lymphocytes also contribute to the inflammatory response. The progression of lung damage is affected by the release of various cytokines and oxidative stress. An increase in proteases is evident in patients with COPD. Proteases may induce breakdown in connective tissue, impairing gas exchange through the mediation of elastin damage and resulting in hypoxemia and hypercapnia. Patients with severe COPD have weak diaphragm tone and diaphragmatic dys-function, requiring ribcage and abdominal muscles to be recruited during inspiration and end-expiration, respectively. The resultant paradoxical breathing leads to a rise in gastric pressure contributing to intrinsic positive end-expiratory pressure (PEEPi). Increased airflow limitation can trigger a COPD exacerbation, resulting in an increased work of breathing, air-trapping, a reduction of chest wall and lung compliance, and PEEPi, which over time will result in respiratory muscle fatigue, increased dead space ventilation, and worsening gas exchange. Increased hypoxemia is also affected by ventilation/perfusion mismatch. Similar to patients with asthma, patients with COPD develop decreased FEV₁ and FVC and a resultant decreased FEV₁/FVC ratio, mildly to non-reversible with bronchodilators. Patients with COPD also develop increases in residual volume and total lung capacity. Genetic risk factors are thought to contribute to the development and magnitude of inflammatory
response, although there are limited and mixed data regarding the genomes identified.\textsuperscript{24} \(\alpha\)-Antitrypsin deficiency has been the most widely studied genetic disease, with focused efforts to target treatment optimization according to genetic predisposition.\textsuperscript{24}

The pathophysiology of patients with severe asthma exacerbations alone differs from that of patients with severe COPD exacerbations, but several characteristics are shared in ACOS. Patients with ACOS have variable airflow obstruction that is not completely reversible.\textsuperscript{11,15,27} In addition, these patients experience increased bronchial hyper-responsiveness. Louie et al. proposed two clinical phenotypes: (1) asthma with partly reversible airflow obstruction and (2) COPD with emphysema accompanied by reversible or partly reversible airflow obstruction.\textsuperscript{28} These phenotypes may then present independently or in a combined fashion represented by eosinophilic bronchiolitis or neutrophilic bronchiolitis.\textsuperscript{28} Airway inflammation is predominantly a result of neutrophil activation. Cytotoxic T lymphocytes, alveolar macrophages, and proteases have also been implicated in ACOS.\textsuperscript{23,28} Some genetic similarities have also been described that influence bronchial hyper-responsiveness and FEV\textsubscript{1}/FVC.\textsuperscript{29}

**Triggers of Acute Severe Exacerbations**

Several triggers are shared in patients with acute severe exacerbations of both asthma and COPD. Among them, medication noncompliance because of educational gap, lack of access to medications, or patient adherence is a leading cause of severe exacerbations. Upper respiratory infections and pneumonia, together with environmental factors such as allergens, are also associated with an increased risk of severe exacerbations.\textsuperscript{1,2} In addition, exercise can induce bronchospasm and hyperinflation,\textsuperscript{5,24} and severe stress has been associated with exacerbations, although the exact mechanism is not well understood.\textsuperscript{5}

Patients with additional comorbidities such as cardiovascular disease or other chronic lung disease, those requiring greater than two
canisters of short-acting β-agonist (SABA) per month, and those with two or more hospitalizations or three or more ED visits for asthma in the past year have a higher likelihood of severe asthma exacerbations. Severe COPD exacerbations may be precipitated by pulmonary thromboembolism, ischemic heart disease, acute heart failure, arrhythmias, alcohol consumption, inactivity, history of reflux or heartburn, and COPD exacerbations themselves. Severe asthma exacerbations may be drug induced secondary to concomitant diseases requiring the use of medications that can disrupt airway patency and increase airway resistance. \( \beta \)-Adrenergic blockers, nonsteroidal anti-inflammatory agents including aspirin, and steroid taper have been associated with bronchospasm.

**Clinical Presentation**

A life-threatening asthma exacerbation is characterized by an inability to speak, a reduced peak expiratory flow rate (PEFR) of less than 25% of a patient’s personal best, and a failed response to frequent bronchodilator administration and intravenous steroids. Often, PEFR and bedside spirometry cannot be performed in these patients. However, if performed, values generally show an FEV\(_1\) or a PEFR less than 25% predicted. Vital sign abnormalities include tachycardia (greater than 120 beats/minute), tachypnea (greater than 30 breaths/minute), and hypotension as intravascular volume depletion worsens secondary to insensible fluid loss. Arterial blood gas may show an acute respiratory alkalosis with normal oxygenation in patients with an asthma exacerbation. In more severe cases, patients will develop a mild or acute respiratory acidosis with a widening A-a gradient indicative of respiratory failure. It is important that these patients be recognized promptly because they are exhausting their accessory muscles, resulting in excessive CO\(_2\) retention. Patients with hypercapnia have wider degrees of pulsus paradoxus, whereas low pulsus paradoxus is indicative of severe hyperinflation, which can result in extracardiac tamponade. Arrhythmias are common in patients with asthma and may be induced secondary to electrolyte disturbances.
abnormalities during management of acute exacerbations with high-dose \(\beta\)-agonist agents.\textsuperscript{38} Some patients may develop a pneumothorax or pneumomediastinum, likely because of increases in intrathoracic pressure, and warrant the need for chest tube placement for decompression.\textsuperscript{5}

Severe COPD exacerbation may develop acutely or for a period of days. Patients generally develop worsening dyspnea, increasing cough, or an increase or change in sputum production from baseline as a result of increased inflammation. Physically, patients tend to appear in acute distress. Presentation with fatigue, weight loss, and anorexia is common in patients with severe COPD.\textsuperscript{24,39} Tachypnea, tachycardia, and decreased blood pressure secondary to PEEPi are common vital sign abnormalities. Respiratory acidosis also develops in acute exacerbations. Use of accessory inspiratory muscles is indicative of increased severity, and paradoxical breathing is associated with a poor prognosis, leading to impending respiratory failure and arrest.\textsuperscript{24,40} Patients with severe hypoxemia may present cyanotic and/or comatose. Development of hypercapnic respiratory failure with preserved ventilation/perfusion match indicates the need for mechanical ventilation.\textsuperscript{26}

---

**ICU ADMISSION**

Severity of illness warranting ICU admission for asthma may include presentation of dyspnea refractory to aggressive bronchodilator therapy, pneumonia, pneumothorax, PEFR less than 40% predicted personal best or lack of adequate response despite aggressive treatment, hypercarbia (partial pressure of carbon dioxide in the blood \([\text{Paco}_2]\) greater than 45 mm Hg), hypoxemia (partial pressure of oxygen in the blood \([\text{Pao}_2]\) less than 60 mm Hg on room air) requiring oxygen supplementation, or a combination of these factors. A history of several ED visits and tracheal intubation secondary to asthma are additional risk factors for asthma-related mortality. In addition, the absence of wheezing implying minimal air movement, use of accessory muscles, a decrease in systolic blood pressure during inspiration by
greater than 15 mm Hg, bradycardia, diaphoresis, cyanosis, anxiety, and inability to talk imply severe obstruction.\textsuperscript{31,41–43}

The severity of COPD may be assessed using the staging criteria developed by the American Thoracic Society and GOLD, which classifies patients into four categories: stage I (mild), stage II (moderate), stage III (severe), and stage IV (very severe) according to the level of obstruction as defined by FEV\textsubscript{1}.\textsuperscript{24} In addition to baseline COPD severity, frequent exacerbations that require hospitalization, several comorbidities, and previous need for mechanical ventilation are risk factors for more severe exacerbations. Early warning scores have also been developed to assist in the triage for ICU admission and taking into consideration parameters associated with poor prognosis.\textsuperscript{44} Factors influencing ICU admission include severe dyspnea refractory to initial aggressive therapy, mental status changes, persistent or worsening hypoxemia, persistent or worsening respiratory acidosis, hemo-dynamic instability, and the need for mechanical ventilation.\textsuperscript{24,26} The treatment algorithms for severe asthma and COPD exacerbations are shown in Figure 31.1 and Figure 31.2, respectively. Comparative therapeutic management of severe exacerbations for patients with asthma and COPD admitted to the ICU is outlined in Table 31.1.

Supportive respiratory care can be provided in different levels according to patient needs. Critically ill patients may require oxygen therapy, noninvasive ventilation (NIV), or invasive mechanical ventilation. This section will provide a brief overview of these supportive therapy options.
Figure 31.1 Severe asthma exacerbation treatment algorithm.\textsuperscript{a}

\textsuperscript{a}See Table 31.1 for dosing recommendations.

\textsuperscript{b}Not available in the United States.

IV = intravenous; SABA = short-acting β-agonist.
Oxygen therapy is an important component in the management of severe asthma and COPD exacerbations. Patients experiencing severe exacerbations of either etiology often present with hypoxemia and require supplemental oxygen. The current asthma guidelines recommend the administration of oxygen by nasal cannula or mask in order to achieve oxygen saturation (Sao₂) values greater than 90%. Other patient populations such as pregnant women and individuals with a cardiac history may have higher oxygen requirements, so an Sao₂ of greater than 95% is often desired in these patients. In COPD, the target oxygen saturation is 88%–92%, which is partly based on data analyses that show patients who received oxygen therapy titrated to a saturation of 88%–92% had lower mortality than those administered high-flow oxygen therapy. Caution is advised with oxygen.
supplementation in patients with COPD, however, because many of these patients rely on a slight level of hypoxemia as a trigger for their respiratory drive secondary to chronic hypercapnia.\textsuperscript{45} In addition, it is important to monitor the degree of oxygen supplementation in these patients, because too much oxygen may also increase ventilation/perfusion mismatch by inducing vasodilation to areas not previously well ventilated, decrease respiratory rate centrally (O\textsubscript{2} retainers are very sensitive to O\textsubscript{2}), and perpetuate the Haldane effect.

Inhaled medications are often administered through nebulizers with the use of oxygen to enhance drug delivery to the lower airways, especially in patients with severe airway restriction. It is important to monitor the fractional concentration of oxygen administered to these critically ill patients, given that this may be more harmful than beneficial to these patients. A study by Chien et al. found that patients who received 100% oxygen had elevations in Paco\textsubscript{2}, and patients with more severe airway obstructions often had more hypercarbia, thereby increasing their risk of respiratory depression secondary to CO\textsubscript{2} retention.\textsuperscript{47,73}

**Noninvasive Ventilation**
Noninvasive ventilation may be an option for patients with severe COPD exacerbation, although its potential benefit in asthma exacerbations remains unclear.\textsuperscript{3,74} In patients with hypercapnia and acute respiratory failure secondary to COPD exacerbation, NIV improves mortality and respiratory acidosis and decreases the need for intubation and treatment failures.\textsuperscript{75,76} Noninvasive ventilation also decreases complications associated with invasive mechanical ventilation in patients with COPD, such as ventilator-associated pneumonia and hospital length of stay.\textsuperscript{76} In a recent evaluation of the addition of NIV to standard medical therapy in patients admitted to an ICU for a severe asthma exacerbation, a clear benefit of NIV when added to standard medical therapy was not shown. Overall, the results suggested that adding NIV to standard therapy in patients with asthma reduces inhaled bronchodilator requirements, accelerates improvement
in lung function, and reduces hospital length of stay, but larger studies are needed to further evaluate these findings.\textsuperscript{74}

Although NIV may be appropriate for some patients experiencing a severe asthma exacerbation, data analyses are insufficient for the current guidelines to provide a recommendation regarding its use in severe exacerbations. The GINA guidelines currently recommend proceeding with intubation as soon as it is deemed medically necessary and intubation should not be delayed by the administration of alternative therapies, including NIV.\textsuperscript{5,71}

In patients with COPD, however, NIV should be considered for those with respiratory acidosis and severe dyspnea with increased work of breathing or clinical signs of respiratory muscle fatigue. These may include respiratory accessory muscle use, paradoxical motion of the abdomen, or retraction of the intercostal spaces.\textsuperscript{40} The use of NIV for severe COPD exacerbation is a level A recommendation from the GOLD guidelines.\textsuperscript{24}

**Mechanical Ventilation**

Patients experiencing worsening respiratory failure during a severe exacerbation despite standard medical therapy often require endotracheal intubation and respiratory support with mechanical ventilation. Currently, there are no parameters to suggest when intubation should occur in severe asthma exacerbation; instead, the decision should be based on clinical judgment.\textsuperscript{42,71} Indications for intubation in patients with asthma may include worsening hypoxemia and hypercarbia, hemodynamic instability, altered mental status, and increased work of breathing.\textsuperscript{42,71} Patients with near-fatal asthma can be challenging to intubate and can often have high ventilator requirements because of the high airway resistance and mucus plugging in the distal airways.\textsuperscript{3} The GINA guidelines recommend a ventilator strategy of permissive hypercapnia or controlled hypoventilation, which provides adequate oxygenation and ventilation but decreases the risk of barotrauma secondary to high airway pressures.\textsuperscript{5,71}

Patients with severe COPD exacerbation who are unable to tolerate
NIV or whose NIV therapy fails may be candidates for invasive mechanical ventilation. Other indications for invasive mechanical ventilation include the inability to clear respiratory secretions, respiratory or cardiac arrest, diminished consciousness, massive aspiration, severe hemodynamic instability without response to fluids and vasoactive medications, and severe ventricular arrhythmias. The decision to institute invasive mechanical ventilation in patients with a severe COPD exacerbation should be made depending on the reversibility of the cause of exacerbation, the patient’s wishes, the appropriate resources, the availability of providers with knowledge about ventilator management, and a risk assessment of complications related to invasive ventilation. These complications include ventilator-associated pneumonia, barotrauma, and inability to wean from mechanical ventilation.

---

**ASTHMA**

**Treatment Goals**
The main treatment goals for a severe asthma exacerbation are to correct significant hypoxemia using supplemental oxygen and to rapidly reverse airflow obstruction with the administration of inhaled SABAs and systemic corticosteroids. Although reducing the risk of future exacerbations is also an important treatment goal, this section will focus on the critical care therapeutic management of life-threatening asthma exacerbations (Figure 31.1).

**Pharmacologic Interventions**

**Bronchodilators**
The current asthma guidelines recommend that all patients experiencing an asthma exacerbation receive a SABA by repeated administration with either a metered dose inhaler (MDI) or nebulization immediately on presentation, which should be continued until resolution
of acute symptoms.\textsuperscript{18,43,47,71} Short-acting $\beta$-agonists stimulate the $\beta_2$-receptors on smooth muscle cells and cause relaxation of respiratory smooth muscle. This relaxation leads to bronchodilation and a decrease in airway obstruction.\textsuperscript{42,47} Selective SABAs (albuterol, levalbuterol, pirbuterol) are recommended in acute exacerbation to decrease the risk of cardiotoxicity that can be associated with high doses of SABAs.\textsuperscript{18,71} Albuterol is the most common bronchodilator administered during severe asthma exacerbations. Dosing and monitoring recommendations are provided in Table 31.1. Theoretically, levalbuterol may have fewer cardiovascular adverse effects than albuterol and may be preferable in severe asthma exacerbations when frequent or large doses are required. However, several studies have failed to show a significant difference in heart rate elevation after the administration of albuterol and levalbuterol.\textsuperscript{18,71,78–81} In addition, the efficacy of levalbuterol when administered as a continuous nebulization has not yet been evaluated.\textsuperscript{18,71,81}

In critically ill patients, it is preferable that SABAs be administered as a nebulizer rather than by an MDI to provide a continuous delivery of medication to the obstructed airways.\textsuperscript{47} Patients who require ICU admission may have severe airway edema and increased mucus production, which can further worsen airway obstruction.\textsuperscript{47} Administering $\beta$-agonists by nebulizer either intermittently or continuously should improve the likelihood that bronchodilators are delivered to the lower airways during an acute exacerbation.\textsuperscript{47} Several studies have evaluated the effects of continuous versus intermittent nebulization on pulmonary function in patients presenting to the ED. A meta-analysis of eight studies, most of which enrolled only adults, found that patients who received continuous nebulization of SABAs in the ED had an improvement in their pulmonary function tests (PEFR and FEV\textsubscript{1}) after 2–3 hours of therapy. Patients with severe acute exacerbations were found to specifically benefit from continuous nebulization of SABAs, but additional studies are needed to confirm these findings.\textsuperscript{46}

Studies have found that systemic $\beta$-agonists, such as intravenous or subcutaneous epinephrine or terbutaline, are not more efficacious than
inhaled β-agonists in the management of an acute asthma exacerbation, and it is possible that they are associated with more cardiovascular adverse effects. Critically ill patients may benefit from systemic administration of β-agonists if they lack a good response to inhaled SABA therapy or if they are unable to receive inhaled medications, although data evaluations have not shown improved outcomes with this approach. Long-acting β-agonists (LABAs) in combination with inhaled glucocorticoids have been shown to be effective in preventing asthma exacerbations, but their use in the treatment of severe acute exacerbations has not been demonstrated.

Inhaled Anticholinergic Agents
Inhaled anticholinergic medications such as ipratropium bromide cause bronchodilation by selectively binding to the muscarinic receptors on smooth muscle cells in the airways and reducing bronchoconstriction. Administration of ipratropium in addition to a SABA is recommended to promote additional bronchodilation through a different pathway. Studies have not found a significant benefit when ipratropium is continued after the initial doses are given in the ED, but it is often common practice to continue the administration of ipratropium with a SABA in critically ill patients. Targeting different sites and mechanisms of airway bronchodilation with different medications may benefit patients who experience severe bronchoconstriction and require ICU admission for an acute asthma exacerbation.

Corticosteroids
Systemic corticosteroids are recommended in patients who have an incomplete response to the initial administration of an inhaled SABA, and they should be continued during hospital admission. Corticosteroids decrease airway obstruction during an asthma exacerbation by decreasing inflammation, increasing the number of β2-receptors and increasing their responsiveness to β-agonists, reducing airway edema, and suppressing certain proinflammatory cytokines by interfering with the regulation of their transcription. A meta-
analysis evaluating the use of corticosteroids in patients presenting to the ED found that patients who received corticosteroids had an increase in PEFR at the end of treatment.\textsuperscript{48} There was often a delay in the improvement of pulmonary function after the administration of corticosteroids in these studies, so it is recommended that corticosteroids be initiated within the first hour of presentation.\textsuperscript{47,48} An additional meta-analysis evaluated the effects of varying doses of corticosteroids in hospitalized patients and found that there was no added benefit to improvement in pulmonary function when doses of methylprednisolone greater than 60–80 mg per day were used. However, none of the studies that were reviewed included patients who required mechanical ventilation or ICU admission.\textsuperscript{83} The exact dose of corticosteroids a patient should receive during an acute exacerbation is not known at this time, but studies have indicated that doses of prednisone greater than 100 mg per day do not provide a significant benefit.\textsuperscript{49} It is recommended that patients receive 60–80 mg per day of prednisone or methylprednisolone during acute exacerbations, followed by a decrease in dose once the patient has signs of improvement in pulmonary function. Corticosteroids should be tapered in patients who require treatment for longer than 1 week unless they only require a 10-day course of systemic corticosteroids and are also on an inhaled corticosteroid (ICS).\textsuperscript{3,5}

Studies have indicated that an ICS may prevent hospital admissions for acute asthma exacerbations compared with placebo, but their role in acute exacerbations is less clear. It is possible that adding an ICS to systemic corticosteroids during an acute exacerbation will improve outcomes, but no data suggest that an ICS alone should be used during an acute exacerbation. In addition, the optimal dosing, delivery, and frequency of ICS administration during an exacerbation are currently unknown and require further evaluation.\textsuperscript{84}

**Intravenous Magnesium Sulfate**

In patients with severe and life-threatening asthma exacerbations, intravenous magnesium sulfate may be beneficial.\textsuperscript{18,71} Magnesium is thought to cause bronchodilation by inhibiting calcium channels on
smooth muscle, which causes relaxation of smooth muscle.\textsuperscript{3,82} Magnesium may also have anti-inflammatory effects by interfering with the activation and release of neutrophils in patients with asthma.\textsuperscript{85,86} A meta-analysis of 14 studies found that patients who received magnesium sulfate as a single intravenous dose of 1.2 or 2 g had improved lung function and decreased hospital admissions when inhaled SABAs and systemic corticosteroids did not provide a sufficient response.\textsuperscript{87} A study by Silverman et al. evaluated the addition of 2 g of intravenous magnesium sulfate to nebulized albuterol and intravenous methylprednisolone therapy in patients who presented to the ED with a severe acute asthma exacerbation defined by an initial FEV\textsubscript{1} of 30% or less of predicted. There was no difference in the rate of hospital admissions between the groups, but patients who received magnesium had a significantly higher FEV\textsubscript{1} after 240 minutes of the protocol (48.2% of predicted vs. 43.5% of predicted, p<0.05). These investigators further evaluated changes in FEV\textsubscript{1} in patients according to their severity on admission and found that patients with an initial FEV\textsubscript{1} of less than 20% of predicted had the best response after magnesium administration, whereas patients with an FEV\textsubscript{1} of 25%–30% did not appear to benefit as much from intravenous magnesium.\textsuperscript{57} Although it may seem that magnesium could particularly benefit patients experiencing a severe or life-threatening asthma exacerbation, the meta-analysis by Kew et al. was unable to detect a significant difference between three severity subgroups.\textsuperscript{87} Additional studies with clearly defined groups of severity are needed to further determine whether there is a role for intravenous magnesium in the management of severe asthma exacerbations.

\textbf{Ketamine}

Ketamine is an anesthetic agent with bronchodilatory properties that may reduce airway resistance in patients with an acute asthma exacerbation.\textsuperscript{47,59} Ketamine may prevent reuptake of norepinephrine, and the increase in norepinephrine concentrations may stimulate \(\beta_2\) receptors, which will result in increased bronchodilation.\textsuperscript{59} Early studies
found that ketamine reduced bronchospasm in patients when it was used as an anesthetic agent, and it was especially beneficial in patients with a history of severe pulmonary disorders. Several case studies evaluating the use of ketamine in mechanically ventilated patients with severe asthma exacerbations found that ketamine decreased bronchoconstriction and improved oxygenation in these patients. Heshmati and colleagues evaluated the use of ketamine in 11 patients with status asthmaticus who did not respond to standard medical therapy (β-agonists, corticosteroids, and theophylline) and who had not improved after 24 hours of mechanical ventilation. These patients received a 1 mg/kg loading dose of ketamine followed by a continuous infusion at a rate of 1 mg/kg/hour for 2 hours. The investigators found significant improvements in mean peak airway pressures, mean Paco$_2$, and mean Pao$_2$ after completion of the 2-hour infusion, but the lack of a control group does not allow for evaluation of the effects of ketamine on ventilator days or other important variables. Although data are still limited, ketamine may be beneficial in patients with asthma that is refractory to other standard treatments. In addition, ketamine has been recommended for rapid sequence intubation in patients with asthma secondary to its bronchodilatory effects compared with other agents that have potential for bronchoconstriction, although improved outcomes have not been published.

**Heliox**

Heliox is a mixture of about 70%–80% helium and 20%–30% oxygen that results in a very low-density gas that may decrease airway resistance and result in an improvement in airflow and ventilation in patients experiencing an acute asthma exacerbation. A review of 10 studies of heliox administration in nonintubated patients found that heliox was no more effective than oxygen or air delivery in these patients. However, patients with moderate to severe impairment experienced a significant increase in pulmonary function with heliox, so it is possible that heliox provides the most benefit in patients who are experiencing severe airflow resistance during an exacerbation.

Heliox may be more beneficial as a drug-delivery agent because
heliox-driven albuterol may result in the deposition of albuterol into the distal airways of severely restricted patients. A 2002 study by Kress et al. found that patients who received albuterol nebulized with an 80:20 mixture of heliox had an improvement in respiratory function compared with those who only received albuterol nebulized with oxygen. A meta-analysis by Rodrigo and colleagues found that patients who received a SABA nebulized with heliox had a 17.2% increase in mean percentage of change in PEFR from baseline compared with patients who received a β-agonist nebulized with oxygen. They also found that the greatest improvement in PEFR secondary to heliox-driven β-agonist nebulization seemed to occur in the studies that evaluated patients with acute severe exacerbations.

The asthma guidelines currently state that heliox may be beneficial in patients with impending respiratory failure, but its use should not delay intubation in any patient if intubation is needed.

**Therapies to Use with Caution**

**Methylxanthines**
Methylxanthines such as theophylline and aminophylline are no longer recommended by the asthma guidelines because they appear not to provide any additional benefit when administered with adequate doses of a SABA. In addition, methylxanthines have several adverse effects associated with their use, including potential arrhythmias. If a patient is maintained on a methylxanthine at home before being admitted for an acute exacerbation, blood levels should be monitored often.

**Intravenous Leukotriene Receptor Antagonists**
Leukotrienes are inflammatory mediators that play a significant role in airway disease by causing bronchoconstriction, increased mucous production, recruitment of other inflammatory mediators, and proliferation of airway smooth muscle cells. Leukotriene receptor antagonists such as montelukast can promote bronchodilation by reversing the bronchoconstriction and airway inflammation that is
caused by leukotriene mediators.\textsuperscript{47,69} A study evaluating the use of intravenous montelukast in patients with acute asthma, although not yet available in the United States, found that patients who received 7 mg of intravenous montelukast in addition to the standard treatment for an asthma exacerbation had a significant improvement in their FEV\textsubscript{1} compared with patients who only received standard medical therapy.\textsuperscript{69} Although the onset of bronchodilation after intravenous montelukast administration is not as fast as the onset of bronchodilation after inhaled SABAs, it does seem to provide an improvement in bronchodilation within 10–20 minutes of administration and appears to last up to 24 hours.\textsuperscript{69,70} Additional studies are needed to determine the role of leukotriene receptor antagonists in the management of severe asthma exacerbations.

**Special Population Considerations—Pregnancy**

Asthma is a common respiratory condition that affects women during pregnancy. It is estimated that 20% of pregnant women with asthma experience exacerbations that require medical interventions, and up to 6% of those require hospital admission for treatment of their severe exacerbation.\textsuperscript{92,93} Worsening of asthma symptoms occurs most often in the second and third trimesters, with a peak of exacerbations late in the second trimester.\textsuperscript{93,94} Exacerbations rarely occur during the labor and delivery part of pregnancy.\textsuperscript{93} According to Chan et al., ICU admission should be considered for pregnant women who have either an FEV\textsubscript{1} of less than 25% or an FEV\textsubscript{1} that does not improve more than 10% after treatment with a sufficient dose of an inhaled SABA.\textsuperscript{93}

Inhaled SABAs are the mainstay of treatment in pregnant patients with severe asthma exacerbations. Albuterol continues to be the preferred agent in these patients and is generally considered safe to use in pregnancy.\textsuperscript{94} Patients should receive a continuous nebulization of albuterol at a dose of 0.5–1 mg/hour.\textsuperscript{93} Systemic epinephrine should be avoided in these patients because of the increase in uterine vasoconstriction associated with its use. If a systemic β-agonist is needed to improve asthma symptoms in severe exacerbations, it is
recommended that subcutaneous terbutaline be used instead of epinephrine.\textsuperscript{93,95} Patients should also receive systemic corticosteroids, either methylprednisolone or prednisone, at the time of SABA initiation. Enzymes within the placenta metabolize a large percentage of these maternal corticosteroids, so there should be minimal exposure to the fetus during the treatment for asthma exacerbations.\textsuperscript{96} However, there is still the potential for impaired fetal growth development because of exposure to corticosteroids, but the risk of these adverse effects should be weighed against the benefit of corticosteroids to the mother. Intravenous magnesium sulfate can also be administered to pregnant patients to provide additional bronchodilation during an acute exacerbation.\textsuperscript{93}

Pregnant patients should be administered supplemental oxygen to maintain oxygen saturations of at least 95%. If patients experience continued hypoxia despite oxygen supplementation, significant respiratory acidosis, maternal fatigue, or other signs of an increased work of breathing, intubation and mechanical ventilation should be considered.\textsuperscript{93} Permissive hypercapnia should also be used in pregnant patients experiencing an asthma exacerbation as it is used in non-pregnant patients. There is concern about using permissive hypercapnia in pregnant patients because of the potentially negative effects of elevated P\textsubscript{CO}_2 on uterine blood flow as well as the potential for developing fetal respiratory acidosis.\textsuperscript{93} However, as with other therapies, the benefit of permissive hypercapnia to the mother and her survival must be weighed against the potential adverse effects to the fetus.

---

**COPD MANAGEMENT**

**Treatment Goals**

The treatment goals for an acute exacerbation of COPD are two-fold. The first is to provide supportive care and resolve the acute exacerbation with minimal impact on the patient’s lung function, and the second is to prevent future exacerbations.\textsuperscript{97} Both of these goals are
important in the treatment of patients with COPD and are therefore common end points used in clinical trials. This chapter will primarily focus on the resolution of the exacerbation of COPD in the critically ill patient and successful discharge from the ICU (Figure 31.2), but it is important to note the therapies that are associated with prolonged time to next exacerbation as well.

**Pharmacologic Interventions**

**Bronchodilators**

Short-acting inhaled β-agonists with or without short-acting inhaled anticholinergic agents are the preferred agents for bronchodilation in COPD exacerbation. Short-acting bronchodilators are often used in increasing doses and frequencies to provide symptomatic relief. Dosing and monitoring recommendations are provided in Table 31.1. Despite their widespread acceptance, the use of these agents is a level of evidence C recommendation in the GOLD guidelines because of the lack of controlled trials examining their efficacy in COPD exacerbation management. A meta-analysis of 12 studies comparing the delivery of short-acting bronchodilators by MDI and nebulization found no difference in efficacy in patients with an acute airflow obstruction (p>0.05). Similar results were seen in the subgroup analysis of patients with COPD exacerbation. Most studies used spacers with MDIs, although they may not be necessary for adequate drug delivery. Nebulization may be a more convenient route of delivery for critically ill patients or those who are unable to hold their breath after actuation of an MDI because of severe dyspnea.

**Methylxanthines**[^66-68]

| Recommendation | Not recommended but may continue in patients who are maintained on them at home | Second-line therapy if lack of response to short-acting inhaled bronchodilators |
| Dosing | Aminophylline 6 mg/kg IV load; then 0.5–0.9 mg/kg/hr IV infusion |
| Outcome | Benefits outweighed by risk of adverse effects | No benefit in clinical outcomes, FEV₁, FVC, or ventilation/perfusion, but increase in AEs |
| Monitoring | Plasma concentration, heart rate, respiratory rate |

**Intravenous Leukotriene Receptor Antagonists**[^69,70]

| Recommendation | May benefit patients with severe asthma but not currently available for use in the United States | No recommendation |
| Dosing | One dose of IV montelukast 7 |
| **Monitoring** | Plasma concentrations, heart rate, respiratory rate |

[^66-68]: Methylxanthines
[^69,70]: Intravenous Leukotriene Receptor Antagonists
Long-acting β-agonists and anticholinergic agents have been shown to reduce exacerbations, but their role in an acute exacerbation remains unclear. An unblinded randomized controlled pilot study compared indacaterol (a LABA) daily with salbutamol (a SABA) three times a day, in addition to standard therapy, in 29 patients admitted to the ED. The authors found that the patients in the indacaterol group had more improvement in pulmonary function (FEV$_1$, PEFR) and $P_{O_2}/F_{I O_2}$ (fraction of inspired oxygen) ratio than did the patients in the traditional salbutamol therapy group. The results of this study suggest that LABAs have a role in COPD exacerbation. However, this study did not include critically ill patients, and the administration of LABAs to critically ill patients may not always be feasible because LABAs are primarily available as dry powder inhalers that are not compatible with ventilators or may be difficult to use for patients with severe respiratory distress.

**Corticosteroids**
The use of corticosteroids in COPD exacerbations is a mainstay of therapy to decrease the systemic and local inflammation. The use of
systemic corticosteroids in COPD exacerbation is recommended by the GOLD guidelines (level of evidence A).\textsuperscript{24} Corticosteroids have been associated with improved FEV\textsubscript{1}, decreased treatment failures, and reduced hospital length of stay.\textsuperscript{100–102}

Unfortunately, the optimal dose and duration of corticosteroids remains under debate, especially in the critically ill population. The dose recommended by the GOLD guidelines is 40 mg of prednisone equivalent daily (preferably oral) for 5 days; however, this recommendation is largely based on studies that do not include critically ill patients. A randomized, double-blind trial including 83 patients 18 years and older with COPD exacerbation requiring hospitalization and ventilator support (invasive or NIV) compared methylprednisolone 0.5 mg/kg intravenously every 6 hours for 72 hours, 0.5 mg/kg every 12 hours on days 4–6, and 0.5 mg/kg daily on days 7–10 with placebo. The investigators found that the steroid arm had a shorter duration of mechanical ventilation ($p=0.04$), shorter length of ICU stay ($p=0.09$), fewer failures of NIV ($p=0.004$), and more hyperglycemia ($p=0.04$). This study was not powered to detect differences in length of stay or mortality.\textsuperscript{50} Another study of 217 critically ill patients 40 years and older with COPD exacerbation requiring mechanical ventilation compared open-label enteral prednisone 1 mg/kg daily for a maximum of 10 days with a control group. No significant differences in ICU mortality, NIV failure, duration of mechanical ventilation, or ICU length of stay were identified, although the study did not meet power. There was an increase in hyperglycemia in the steroid group ($p=0.015$).\textsuperscript{51} A cohort study by Kiser et al. compared high-dose (more than 240 mg/day) and lower-dose (240 mg/day or less) methylprednisolone in 17,239 patients with COPD exacerbation admitted to an ICU. Patients who received higher-dose methylprednisolone had longer ICU and hospital length of stay, higher hospital costs, longer duration of mechanical ventilation, and more hyperglycemia and fungal infections. There was no difference in mortality between the two groups.\textsuperscript{52}

A recent meta-analysis included trials evaluating systemic corticosteroid use in ICU and non-ICU patient populations. The results
showed improvement in treatment success in the overall population in the corticosteroid group. Treatment success was defined to include the following: (1) clinical improvement as assessed by a questionnaire; (2) improvement in FEV$_1$ or blood gases; (3) reduction in length of hospital stay in acute care patients and lack of need for intubation in patients on NIV or reduced mortality for mechanically ventilated, critically ill patients. No difference was seen in mortality, although only 9 of the 12 articles included mortality as an end point. The number of hyperglycemic episodes was higher in the corticosteroid group. Despite the overall benefit in the ICU subgroup, the use of corticosteroids had no effect on treatment success.\textsuperscript{53} This result should be interpreted with caution, however, because this analysis included only two clinical trials with different study designs, as evidenced by high heterogeneity in this subgroup (I$^2 = 77.4\%$).

An additional consideration in the critically ill population is whether the possibility of altered bioavailability of corticosteroids secondary to hypoxemia or fluid overload should affect the route of administration of these drugs. Inhaled corticosteroids may provide an additional alternative route because they improve lung function and reduce the frequency of COPD exacerbations,\textsuperscript{24} but data regarding their utility in the management of COPD exacerbation are currently lacking.

According to currently available evidence, corticosteroid therapy seems to be beneficial in patients with COPD exacerbation. The two available studies of ICU patients used different dosing strategies for corticosteroids, and the optimal dose remains unknown. It would be reasonable to use the lowest effective dose of corticosteroid with consideration for a relative maximum dose of methylprednisolone 0.5 mg/kg intravenously every 6 hours (2 mg/kg/day). Oral or enteral therapy is preferred if this route of administration is possible, and the duration of therapy should be limited to a maximum of 10 days to minimize adverse effects.\textsuperscript{24}

**Antimicrobial Therapy**

Chronic obstructive pulmonary disease exacerbation caused by an infection may be of a bacterial or viral etiology.\textsuperscript{24} Bacteria represent
40%–50% of COPD exacerbations. The most commonly seen bacteria are Haemophilus influenzae, Streptococcus pneumoniae, and Moraxella catarrhalis. In a recent study evaluating the etiology of COPD exacerbation in patients with severe COPD, the most common bacterial pathogen isolated was Pseudomonas aeruginosa. There was also a notable percentage of isolates (6%) with Staphylococcus aureus, and patients with more frequent exacerbations had a higher likelihood of having Enterobacteriaceae. Atypical bacteria (Chlamydia pneumoniae and Mycoplasma pneumoniae) make up 5%–10% of COPD exacerbations. Viruses are the causative pathogen in 30%–40% of COPD exacerbations. The most commonly seen virus is rhinovirus, followed by parainfluenza, influenza, respiratory syncytial virus, coronavirus, and adenovirus. 

Unfortunately, because of inconsistencies in clinical trial design, including the definition of COPD exacerbation, exclusion of subjects with pneumonia, and lack of placebo-controlled arm, the routine use of antibiotics for COPD exacerbation is controversial. A meta-analysis found that antibiotics in COPD exacerbation were beneficial and decreased the incidence of treatment failure, but they had no effect on mortality or hospital length of stay. An ongoing clinical trial is evaluating the need for antibiotic therapy in moderate exacerbation of COPD in an attempt to answer this controversial question. Therapy with antibiotics is currently recommended by the GOLD guidelines for patients who have the three cardinal symptoms: increase in dyspnea, sputum production, and sputum purulence (level B recommendation). In patients with severe COPD exacerbation, particularly those who require either noninvasive or invasive ventilation, the indication for antibiotic therapy is slightly clearer. A randomized controlled trial was conducted to evaluate the use of ofloxacin in patients with COPD exacerbation requiring mechanical ventilation. The results of this study showed a reduction in mortality in the ofloxacin group compared with placebo of 4% versus 22%, respectively (p=0.01), as well as a significant reduction in the need for additional antibiotics, duration of mechanical ventilation, and length of hospital stay. Another study compared amoxicillin/clavulanic acid with placebo in patients with
COPD exacerbation. The results of a subgroup analysis of patients with severe COPD at baseline showed a significant improvement in FEV$_1$ after antibiotic treatment ($p<0.01$). The use of antibiotics in patients with COPD exacerbation requiring mechanical ventilation (invasive or noninvasive) is a level B recommendation in the GOLD guidelines.

Although the ideal treatment remains to be determined, the evidence supports the use of antibiotic therapy in critically ill patients with severe COPD exacerbations. Table 31.1 outlines antibiotic considerations according to common pathogens; however, therapy should be selected according to local susceptibility patterns of antibiotics to target the aforementioned pathogens, with consideration for coverage of Pseudomonas spp. and Enterobacteriaceae in certain patients. The length of therapy recommended by the guidelines is 5–10 days (level of evidence D).

**Heliox**

As mentioned earlier in this chapter, heliox is a mixture of helium and oxygen that results in a lower-density gas and may reduce resistance in the airways where airflow is turbulent. However, because COPD largely affects the small airways in the lungs, where flow is laminar rather than turbulent, the effect of heliox theoretically may not be as pronounced as in patients with asthma. A prospective study of 25 mechanically ventilated patients with COPD exacerbation evaluated the effect of heliox on respiratory and hemodynamic parameters at baseline, during heliox treatment, and after heliox treatment. The results showed a significant improvement in PEEPi, trapped lung volume, and cardiac performance. The authors concluded that heliox may be a useful adjunct for patients with severe COPD exacerbation and high PEEPi causing systolic pressure variations. A review of the use of heliox for COPD exacerbation mentions successful case reports/case series of heliox improving hypercapnia and avoiding intubation. In mechanically ventilated patients, small studies had conflicting results, with some showing improved work of breathing and decreased auto-PEEP and others showing an inconsistent or lack of
benefit. Overall, the author did not recommend the use of heliox because of a lack of robust data and limited availability of the heliox delivery system.\textsuperscript{65}

Heliox was also studied as a driving gas for administering the SABA salbutamol and budesonide with the hypothesis that it would be beneficial for drug delivery to the small airways and alveoli. This prospective, randomized trial found no difference in \( \text{Pao}_2 \), \( \text{Paco}_2 \), \( \text{FEV}_1 \), or \( \text{FVC} \), which suggests a limited benefit of using heliox to improve drug delivery in COPD exacerbation, although the sample size was small (n=30).\textsuperscript{107} Heliox may be a beneficial adjunct therapy in select patient populations, such as those with high auto-PEEP or impending hypercapnic respiratory failure, but more evidence is needed before heliox can be a routinely recommended therapy.

**Intravenous Magnesium Sulfate**

Magnesium may be beneficial in COPD exacerbation because of its bronchodilatory effect, which is thought to be due to bronchial smooth muscle relaxation. In a review of four randomized trials, the authors found that intravenous magnesium had no significant effect on bronchodilation, but they did note an improvement in \( \text{FEV}_1 \) after an inhaled SABA was administered in the magnesium group compared with the control group, and magnesium use after SABA administration was associated with an increased PEFR.\textsuperscript{58} The use of magnesium is not currently recommended by the guidelines, and further investigative controlled trials are needed before its use can be routinely recommended.

**Therapies to Use with Caution**

**Methylxanthines**

Intravenous methylxanthines may be considered in patients with an inadequate response to short-acting inhaled bronchodilators and are considered second-line therapy. This is a level B recommendation from the GOLD guidelines.\textsuperscript{24} Studies examining the use of intravenous
Aminophylline in COPD exacerbation did not find any significant benefit in clinical outcomes (including dyspnea and length of hospital stay), FEV\(_1\), FVC, or ventilation/perfusion. However, these studies did find a statistically significant increase in adverse effects with aminophylline, including nausea/vomiting, tremor, tachycardia, and diarrhea.\(^{66-68}\) According to the currently available data, methylxanthines should not be routinely used for COPD exacerbation.

**Doxapram**

Doxapram is a respiratory stimulant that has been used to treat respiratory failure in COPD exacerbation. It works by stimulating respiration by acting on central and peripheral chemoreceptors and causing an increased tidal volume. A review of randomized trials found that doxapram may be slightly better than placebo in improving oxygenation and correcting respiratory acidosis. When doxapram was compared with NIV, the results were conflicting, with one study showing better blood gases in the NIV group and another showing no difference.\(^{108}\) Current evidence does not support the use of doxapram and other respiratory stimulants, and their use is not recommended by the current guidelines.\(^{24}\)

**ASTHMA-CHRONIC OBSTRUCTIVE PULMONARY DISEASE OVERLAP SYNDROME**

Patients with ACOS have a higher rate of exacerbation and likely a higher disease severity.\(^{15}\) A joint project by GINA and GOLD sought to provide treatment guidance according to the differentiating features of ACOS; however, therapeutic management in ICU patients has not been delineated.\(^{11}\) Given the characteristics of ACOS, patients should be treated with systemic corticosteroids, SABAs, and short-acting inhaled anticholinergics. Because ACOS features resemble those of asthma and COPD, it is likely that these patients will also benefit from other bronchodilator therapies mentioned in this chapter, although data are insufficient to provide recommendations at this time. Patients with ACOS exacerbation should also be assessed for infectious causes of
their exacerbation and should be treated accordingly using clinical judgment. Targeted recommendations for ACOS exacerbation require further investigation.

Section 8

Cardiovascular Critical Care
LEARNING OBJECTIVES

1. Describe the pathophysiology, epidemiology, and etiology of acute decompensated heart failure (ADHF).

2. Identify prognostic factors (hemodynamic subsets) that can be used to stratify patients with ADHF by risk for unfavorable outcomes.

3. Recommend an initial diuretic strategy to treat individual patients with ADHF experiencing volume overload, including the role of intravenous vasodilators for acute dyspnea relief.

4. Evaluate therapeutic options for treating patients with ADHF demonstrating refractoriness to intravenous diuretic therapy, including the role of adjunct diuretics, vasopressin receptor antagonists, and ultrafiltration.

5. Differentiate the role of vasodilators and inotropes for the management of ADHF.

6. Advocate for the appropriate use of guideline-driven medical therapies during ADHF episodes, including when to continue and discontinue such therapies.

7. Recognize the role of cardiac transplantation and various types of mechanical circulatory support (intra-aortic balloon pump, temporary and permanent ventricular assist devices, and
extracorporeal membrane oxygenation) in ADHF management.

ABBREVIATIONS IN THIS CHAPTER

ACE  Angiotensin-converting enzyme
ADHF  Acute decompensated heart failure
BNP  B-type or brain natriuretic peptide
GDMT  Guideline-directed medical therapy
GI  Gastrointestinal
IABP  Intra-aortic balloon pump
LV  Left ventricular
LVAD  Left ventricular assist device
MCS  Mechanical circulatory support
PA  Pulmonary artery
PCWP  Pulmonary capillary wedge pressure
RV  Right ventricular
VAD  Ventricular assist device

INTRODUCTION

Acute decompensated heart failure (ADHF) is a clinical diagnosis characterized by the emergence of new or worsening signs and/or symptoms of heart failure. Most ADHF cases require escalated medical care, although prompt management may prevent the need for admission to an intensive care unit. Patients with ADHF may present with signs and symptoms consistent with volume overload, reduced
tissue perfusion, or both, regardless of whether the exacerbation occurs in the context of heart failure with reduced ejection fraction (formerly known as systolic dysfunction) or heart failure with preserved ejection fraction (formerly known as diastolic dysfunction). An exacerbation of ADHF may also be classified by the ventricular chamber affected (i.e., right heart failure, left heart failure, or biventricular failure). Cardiogenic shock is differentiated from ADHF by the presence of systemic hypoperfusion, which often manifests clinically as end-organ dysfunction.

The number of patients with heart failure is expected to increase by almost 50% by 2030.\textsuperscript{1} Heart failure represents up to 3% of all hospitalizations in the United States, resulting in more than 3 million hospitalizations annually; in patients older than 65 years, heart failure represents the most common reason for hospital admission.\textsuperscript{2} Following hospital discharge, the risk of early readmission for heart failure remains unacceptably high and has been highlighted as a key quality measure with significant financial implications.\textsuperscript{3} Consequently, patients with ADHF should receive extensive postdischarge care and planning in addition to the acute interventions necessary to improve symptoms, restore hemodynamic stability, and reduce the risk of in-hospital morbidity and mortality.

The pathophysiology of ADHF depends in part on the underlying etiology of chronic heart failure. Insulting factors that can destabilize a patient with chronic heart failure include those that increase fluid retention and thus signs and symptoms of congestion (e.g., excess fluid intake, nonadherence to diet or diuretic therapy), enhance the excess neurohormonal activation responsible for chronic heart failure (e.g., nonadherence to inhibitors of the reninangiotensin-aldosterone system or sympathetic nervous system), and impair cardiac output (e.g., acute myocardial infarction, arrhythmias). In addition, patients may present with progressive worsening of cardiac output, despite guideline-directed medical therapy (GDMT); these patients should be evaluated for advanced therapies (e.g., cardiac transplantation). Often, the reason for an acute exacerbation is multifactorial, and patients with more advanced heart failure can experience acute decompensation
after even a relatively mild insult.

**CLINICAL PRESENTATION**

**Hemodynamic Subsets**

**Classification by Signs and Symptoms**
The diagnosis of ADHF should be based primarily on signs and symptoms. Volume overload is the most common presentation of ADHF, and the sign and symptom that best correlate with volume status are jugular venous distension and orthopnea, respectively. Although an S3 gallop is very specific for volume overload, pulmonary crackles and lower extremity edema have low specificity and sensitivity.

Medical management of ADHF is determined by differentiating whether the patient has signs and symptoms of fluid overload or hypoperfusion. Patients with volume overload may present with pulmonary congestion (orthopnea, dyspnea with minimal exertion), systemic congestion (gastrointestinal [GI] discomfort, ascites, and peripheral edema), or both. In contrast, hypoperfusion commonly presents as extreme fatigue with hypotension, narrow pulse pressure, worsening renal function, cool extremities, or poor mentation. Gastrointestinal symptoms (e.g., nausea, vomiting, early cachexia) may result from GI edema secondary to volume overload or hypoperfusion of the GI tract. In patients with both volume overload and hypoperfusion, low-output symptoms may not be obvious until congestion is optimally managed.

**Classification by Hemodynamic Monitoring**
As shown in the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE), routine placement of a pulmonary artery (PA) catheter does not affect survival and is therefore not indicated in a broad population of patients with ADHF. However, invasive hemodynamic monitoring with a PA catheter
may be considered in patients who have respiratory distress or hypoperfusion and in whom cardiac filling pressures cannot be readily ascertained. In addition, invasive monitoring may be considered in select patients who are persistently symptomatic despite standard therapies; have uncertain fluid or hemodynamic status, low systolic blood pressure or symptomatic hypotension, worsening renal function, or a requirement for intravenous vasoactive therapy; or are being evaluated for mechanical circulatory support (MCS) or cardiac transplantation. Of importance, in each of these cases, the level of evidence for invasive hemodynamic monitoring remains expert opinion. Nonetheless, it may assist in classifying patients into a hemodynamic subset as well as selecting appropriate medical therapy.

Hemodynamic monitoring is typically performed with a flow-directed PA catheter (also known as a Swan-Ganz catheter) placed percutaneously through a central vein. The catheter is advanced through the right atrium and ventricle and into the PA. At the proximal end of the catheter, a balloon may be periodically inflated to “wedge” the balloon in a pulmonary capillary, yielding the PA occlusion pressure or pulmonary capillary wedge pressure (PCWP). In the absence of certain cardiac structural abnormalities (e.g., mitral valve disease) or pulmonary disease, this pressure estimates the left atrial or pulmonary venous pressure and left ventricular (LV) end-diastolic pressure. The PCWP reflects preload and is a useful marker of volume status; an elevated PCWP indicates volume overload, whereas a reduced PCWP indicates intravascular volume depletion or inadequate filling pressures. According to the Frank-Starling curve, a PCWP of 6–12 mm Hg is desirable in normal patients, whereas a PCWP of 15–18 mm Hg is commonly required in patients with heart failure to ensure adequate stroke volume.

Cardiac output may also be measured with a PA catheter; 4–6 L/minute/m² is considered normal. A more useful clinical parameter is cardiac index (CI), which is the cardiac output normalized for body surface area; 2.8–4.2 L/minute/m² is considered normal, although a CI of 2.2 L/minute/m² in patients with ADHF is usually acceptable. A mixed venous oxygen saturation (SVO₂), which reflects the percentage of
oxygen bound to hemoglobin returning to the right side of the heart, may be obtained from the tip of the PA catheter. The SVO$_2$ represents net oxygen delivery and consumption at the tissue level; 60%–80% is normal, and a low number indicates impaired peripheral blood flow. Because the use of PA catheters has declined since publication of the ESCAPE trial, the SVO$_2$ may also obtained from internal jugular or subclavian catheters.

Finally, systemic vascular resistance may be calculated using parameters obtained from a PA catheter. Systemic vascular resistance represents the sum of forces impeding the ejection of blood from the left ventricle (i.e., afterload) and is therefore inversely related to cardiac output; 800–1200 dyne/sec/cm$^5$ is considered normal. Vasoconstriction increases vascular resistance, whereas vasodilation reduces it. An elevated systemic vascular resistance is common in untreated heart failure and can be managed with intravenous or oral arterial vasodilators. In contrast, a low resistance is consistent with vasodilatory shock (e.g., sepsis) as well as end-stage heart failure.

Patients with ADHF may be classified into four hemodynamic subsets on the basis of a CI above or below 2.2 L/minute/m$^2$ and a PCWP above or below 18 mm Hg (Table 32.1). Patients in the wet-warm (subset II; volume overload but with adequate peripheral perfusion) and wet-cold (subset IV; volume overload and hypoperfusion) profiles have a 2- and 2.5-fold greater risk of death at 1 year, respectively, compared with dry-warm patients.$^{4,8}$ In patients with volume overload (subset II), intravenous administration of agents that reduce preload (e.g., loop diuretics, nitroglycerin) is the most appropriate initial therapy. In patients with hypoperfusion (subset III), therapy may differ depending on initial presentation. If the PCWP is significantly below 15 mm Hg, diuretic therapy should be held and fluid restriction liberalized to increase LV filling pressure, consequently improving CI. In select cases, intravenous fluids may be required. For patients in whom CI remains low despite an optimal Frank-Starling relationship (i.e., end-stage heart failure refractory to GDMT), intravenous inotropic therapy is indicated. Patients with both volume overload and hypoperfusion (subset IV) have the worst prognosis.
Therapy usually involves a combination of the agents used in subsets II and III (i.e., a combination of diuretics and vasodilators or inotropes) to achieve therapeutic goals. Careful monitoring and individualization of drug therapy is imperative in this population (Table 32.1).

**Laboratories**
Plasma B-type or brain natriuretic peptide (BNP) and N-terminal pro-BNP concentrations are positively correlated with the presence of volume overload and heart failure severity. These assays are useful in the differential diagnosis of dyspnea, because a BNP concentration less than 100 pg/mL has a 96% predictive value for excluding heart failure. In addition, an elevated BNP concentration before discharge is associated with an increased risk of poor long-term outcomes. Of importance, any pathophysiologic process that increases right heart pressures elevates BNP; concentrations may also be mildly elevated with advanced age, female sex, and renal dysfunction and reduced in obesity. The utility of serial BNP measurement in managing chronic heart failure remains the subject of ongoing research.

<sup>a</sup> In the absence of cardiac dysfunction, normal range for PCWP is 5–12 mm Hg; higher filling pressures (i.e., 15–18 mm Hg) are necessary in patients with heart failure to optimize CI.

CI = cardiac index; GDMT = guideline-directed medical therapy; MCS = mechanical circulatory support.

Several factors are prognostic for outcomes in patients with ADHF. According to data compiled from the Acute Decompensated Heart Failure National Registry (ADHERE), elevated blood urea nitrogen, low systolic blood pressure, and elevated serum creatinine concentrations were associated with the highest risk of in-hospital mortality; patients with all three features have a 20% risk of in-hospital mortality.<sup>10</sup> Hyponatremia, elevations in troponin I, ischemic etiology, and poor functional capacity are also negative prognostic factors.<sup>11</sup> In the Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) registry, low blood pressure and poor renal function were negative prognostic markers for readmission or death, whereas use of standard heart failure therapies
or placement of an implantable cardioverter-defibrillator at discharge was associated with an improved prognosis.\textsuperscript{12}

\section*{VOLUME MANAGEMENT}

\textbf{Loop Diuretics}

Intravenous loop diuretics are recommended for patients with ADHF and evidence of significant volume overload. Furosemide, bumetanide, and torsemide may be used for this purpose, although furosemide is the most widely used agent. After an intravenous bolus, loop diuretics reduce preload within 5–15 minutes through functional venodilation and later (after more than 20 minutes) by sodium and water excretion. In patients receiving chronic loop diuretic therapy before admission, intravenous loop diuretics should be administered at a dose that equals or exceeds the chronic oral daily dose. According to the results of the Diuretic Optimization Strategies Evaluation (DOSE) trial, initial loop diuretic therapy may be administered as either intermittent boluses or continuous infusion\textsuperscript{7,13} because no differences occurred in the coprimary end points of patient global assessment of symptoms and mean change in serum creatinine when either intermittent bolus versus continuous infusion administration or high versus low dose were compared. However, high doses (2.5 times the oral dose before admission, without accounting for bioavailability) showed greater net fluid loss and change in weight at 72 hours as well as a transient increase in renal dysfunction.\textsuperscript{13}

Among the available loop diuretic agents, bioavailability is the primary difference between oral formulations (Table 32.2), whereas intravenous formulations differ by drug concentration. The latter may be clinically relevant when these agents are administered by continuous infusion, in which case furosemide can be associated with considerable added volume. In light of the DOSE trial, continuous infusions are less often used but may occasionally be necessary to administer very high total daily doses when the dose-response ceiling of bolus administration has been reached.
The rate of diuresis should be closely monitored, with careful measurement of fluid intake and output as well as body weight determined at the same time each day. After a single intravenous bolus of loop diuretic, 250–500 mL of fluid loss should occur within 4 hours. Common 24-hour goals for fluid loss are 1–2 L net negative, although some patients may experience and tolerate greater net fluid loss. Of importance, select patients (e.g., those with poor renal function, low albumin) may only tolerate being net negative less than 1 L/day. Vital signs, daily serum electrolytes, blood urea nitrogen, and serum creatinine should be closely monitored. Dietary sodium and fluid restriction is also warranted. Of importance, the goal PCWP is 15–18 mm Hg in patients with ADHF because of the higher preload necessary to optimize cardiac output (i.e., because of a flatter Frank-Starling curve). Cardiac output may also decline with excess PCWP; thus, improved renal function and enhanced diuresis may occur as elevated filling pressures resolve. This phenomenon may also occur because of reduced renal congestion. An acute reduction in venous return may compromise effective preload in patients with diastolic dysfunction, patients with intravascular depletion, or those in whom the CI is significantly dependent on adequate filling pressure. Of importance, intravascular volume depletion may occur in the setting of rapid diuresis, despite total body volume overload; thus, daily diuresis goals must be highly individualized. Although most patients tolerate a 2 L/day net negative diuresis, some end-stage patients, especially those who are malnourished, may only tolerate ½–1 L/day net negative diuresis. Ototoxicity may be avoided by avoiding rapid infusion rates (greater than 4 mg/minute intravenous bolus) and minimizing other ototoxic agents, such as aminoglycosides. In addition, dose-related adverse effects include hypotension, renal impairment, and electrolyte wasting.

Table 32.2  Loop Diuretics Used in Acute Decompensated Heart Failure
Diuretic Resistance

Adjunct Diuretics
Occasionally, patients have a suboptimal response to high doses of loop diuretics. In patients with ADHF, both pharmacokinetic and pharmacodynamic mechanisms may lead to diuretic resistance. First, delayed absorption may result in concentrations that fail to reach the threshold necessary for producing effective diuresis. In addition, compensatory sodium reabsorption in the distal convoluted tubule may occur as a result of loop diuretic administration; over time, chronic administration of loop diuretics may lead to hypertrophic remodeling of the nephron, which may also increase sodium reabsorption. Finally, reduced cardiac output may limit renal perfusion as well as renal drug delivery.

Table 32.3 Thiazide Diuretics Used in Acute Decompensated Heart Failure
Several strategies have been hypothesized to overcome diuretic resistance. First, higher doses of loop diuretics may be administered to achieve concentrations near the peak of the concentration-response curve. As suggested in Table 32.2, the single dose above which additional response is unlikely to occur (i.e., the ceiling dose) depends on renal function. A second approach for overcoming diuretic resistance is using a continuous intravenous infusion. Although no advantages of initial continuous infusion administration were seen in the DOSE trial, investigators did not enroll patients with diuretic resistance; thus, it is unknown how continuous infusion compares with bolus administration in this population. A third strategy includes adding a second diuretic with a different mechanism of action, such as a thiazide-type diuretic (e.g., oral metolazone, hydrochlorothiazide, or chlorthalidone; or intravenous chlorothiazide; Table 32.3), to produce a synergistic diuretic effect. Sequential nephron blockade with a loop and thiazide diuretic should generally be reserved for hospitalized patients because severe electrolyte and volume depletion may occur. Given the cost associated with intravenous chlorothiazide, oral thiazide diuretics should be considered first line.

**Intravenous Vasodilators**

In the absence of symptomatic hypotension, intravenous venodilators such as nitroglycerin and nesiritide may be used in addition to diuretics to aid in acute dyspnea relief.\textsuperscript{7,15} Intravenous vasodilator therapy will
be discussed in detail later in this chapter.

**Dopamine**

Despite mounting evidence that dopamine imparts no benefit in patients with ADHF, its use remains common in select scenarios. As in other critical care settings, lower doses of dopamine (less than 3 mcg/kg/minute) were once theorized to improve renal impairment in the setting of ADHF because of the activation of renal dopaminergic receptors\(^ {16}\); however, this has since been discredited in several randomized controlled trials.\(^ {17,18}\) When added to low-dose furosemide (5 mg/hour) in the Dopamine in Acute De-compensated Heart Failure (DAD-HF) trial, dopamine at doses of 5 mcg/kg/minute provided the same degree of diuresis as high-dose furosemide (20 mg/hour) with no deleterious impact on renal function.\(^ {16}\) However, in the second Dopamine in Acute Decompensated Heart Failure (DADHF II) trial, no differences were demonstrated when the same combination of low-dose furosemide and dopamine was compared with low-dose furosemide alone, suggesting that dopamine had no impact on diuresis or other renal outcomes.\(^ {17}\) A similar lack of benefit was shown in the Renal Optimization Strategies Evaluation (ROSE) trial, when patients with ADHF and renal impairment were randomized to low-dose dopamine (2 mcg/kg/minute) or placebo in a randomized controlled fashion.\(^ {18}\)

Anecdotal reports of improved renal function with dopamine in practice are likely a result of its inotropic effects in ADHF, which have been observed even at low doses.\(^ {19}\) However, using dopamine for this purpose is unlikely to provide any additional benefit over traditional inotropes and it may increase tachyarrhythmias by comparison. Although low-dose dopamine is still included as a recommendation for augmenting diuresis in clinical practice guidelines, this recommendation may change when the results of DAD-HF II and ROSE are integrated into future editions.\(^ {7}\)

**Vasopressin Receptor Antagonists**

Reduced cardiac output may lead to excess stimulation of arterial
baroreceptors, which results in enhanced arginine vasopressin secretion and water retention. Consequently, many patients with heart failure present with some degree of hypervolemic hyponatremia, although its prevalence and severity varies. Hyponatremia is commonly mild, asymptomatic, and self-limited, but patients may present with lethargy, confusion, respiratory arrest, cerebral edema, seizures, coma, or death. Indeed, hyponatremia has been associated with increased mortality in this population.\textsuperscript{20} The primary strategy for managing hyponatremia in heart failure is to manage volume overload with fluid restriction and diuretic administration. Although a combination of hypertonic saline and loop diuretic therapy has been associated with improved hyponatremia without a deleterious impact on volume status, this strategy is not commonly used.\textsuperscript{21} Vasopressin antagonists are therefore an alternative for patients with severe hyponatremia who are refractory to initial measures or who develop neurologic symptoms. Of importance, rapid correction of hyponatremia (greater than 12 mmol/L within 24 hours) should be avoided.\textsuperscript{22}

Tolvaptan is an oral inhibitor of vasopressin-2 $V_2$ receptors in renal tubules, where it prevents the formation of aquaporins and thus inhibits free water reabsorption; it is indicated for managing hypervolemic and euvolemic hyponatremia associated with heart failure and other select diseases. Conivaptan, an intravenous inhibitor of $V_2$ and $V_{1a}$ receptors in vascular smooth muscle, is only indicated for euvolemic hyponatremia. Despite being available orally, tolvaptan should be initiated in the hospital to allow for close monitoring and to avoid an overly rapid rise in serum sodium. Of note, hyponatremia recurs after discontinuing therapy with tolvaptan, suggesting it has no impact on underlying pathophysiology.\textsuperscript{23} In the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) trial, patients hospitalized with New York Heart Association class III–IV heart failure were randomized to treatment with tolvaptan or placebo. Tolvaptan was associated with improvement in hyponatremia, diuresis, and some symptoms of congestion; however, global clinical status at discharge, mortality, or heart failure readmissions were unchanged.\textsuperscript{24,25} Consequently, vasopressin antagonists should be reserved for patients
with ADHF and volume overload who have persistent severe hyponatremia and are at risk of having cognitive symptoms despite water restriction and optimization of GDMT.\textsuperscript{7}

**Ultrafiltration**
Ultrafiltration had previously emerged as an alternative strategy for rapid volume removal, given that salt and water may be eliminated at rates of up to 500 mL/hour. Because of its isotonic method of volume removal, ultrafiltration was surmised to provide a safe and effective approach to improving congestion while avoiding the adverse effects of diuretic therapy, such as hemodynamic perturbations, electrolyte loss, and renal impairment. In patients with ADHF and volume overload, the Ultrafiltration versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) trial suggested that ultrafiltration improved weight loss and net fluid loss compared with intravenous diuretics, as well as reduced readmissions and urgent office or emergency department visits.\textsuperscript{26} However, in the Cardiorenal Rescue Study in Acute De-compensated Heart Failure (CARRESS-HF) trial, a more recent study of patients with ADHF, persistent congestion, and renal impairment; an algorithm of stepped pharmacologic therapy (i.e., loop diuretics, thiazide-type diuretics, vasodilators, and inotropes) was superior to ultrafiltration at preserving renal function with a similar amount of weight loss.\textsuperscript{27} Ultrafiltration was also associated with a higher rate of adverse events, including infections and bleeding complications. Consequently, ultrafiltration may be considered to alleviate congestive symptoms and fluid weight in patients with obvious volume overload or in those refractory to medical therapy.\textsuperscript{7}

**HEMODYNAMIC SUPPORT**

**Vasodilators**
Vasodilators may exert benefit in patients with ADHF through several mechanisms. First, venous dilatation can improve refractory congestive
symptoms by helping mobilize fluid and enhancing diuresis. In addition, dilating the venous vasculature may improve end-organ function by relieving the deleterious impact of excess venous congestion on the liver, kidneys, and GI tract. For patients whose congestion impairs the Frank-Starling relationship, enhanced volume removal with vasodilators in conjunction with diuretic therapy may restore optimal preload conditions. For vasodilators with effects on the arterial vasculature, reducing the excess systemic vascular resistance imparted by the sympathetic nervous system and renin-angiotensin-aldosterone system can confer improved LV performance as a result of reduced afterload. Although reductions in systemic vascular resistance can significantly reduce blood pressure in patients with normal LV function, improved LV performance as the result of reduced afterload in patients with impaired LV function may lead to minimal changes in mean arterial pressure.

BNP = B-type or brain natriuretic peptide; NO = nitric oxide.

Although oral vasodilators such as long-acting nitrates (e.g.,
isosorbide dinitrate), hydralazine, and angiotensin-converting enzyme (ACE) inhibitors are often used in patients with ADHF, the focus of this chapter will be the continuous infusions unique to this setting. Intravenous vasodilators used in ADHF include nitroglycerin, sodium nitroprusside, and nesiritide, each of which differs slightly in pharmacologic and pharmacokinetic effects (summarized in Table 32.4). Nitroglycerin acts almost exclusively as a venous dilator except at high doses (greater than 100 mcg/minute). Consequently, nitroglycerin is usually reserved for relieving venous congestion and improving refractory congestive symptoms. Sodium nitroprusside and nesiritide act as both venous and arterial vasodilators throughout their respective dosing ranges and may therefore improve LV performance through beneficial reductions in afterload, in addition to improving venous congestion. Although BNP should expectedly produce increased urine output through natriuresis, clinical trials (discussed below) do not suggest that this additional property of nesiritide imparts any clinically meaningful effect. From a pharmacokinetic standpoint, the effects of nitroglycerin and nitroprusside may be seen within minutes, whereas the onset of nesiritide may be delayed by up to 15–20 minutes. Nesiritide also has a longer half-life, which may make it more problematic in patients who develop hypotension.

The presence of relative hypotension (i.e., systolic blood pressure less than 90 mm Hg) precludes vasodilator use in many patients with ADHF. As discussed previously, invasive hemodynamic monitoring with a PA catheter can confirm reduced cardiac output in the setting of an elevated systemic vascular resistance, where vasodilator use may still be beneficial despite low systemic pressures. With the exception of nesiritide, prospective studies of vasodilator use in ADHF are limited. In the Acute Decompensated Heart Failure National Registry (ADHERE) assessing the in-hospital mortality of patients with ADHF, nitroglycerin and nesiritide were associated with lower mortality than inotropes but were similar when compared with each other. In a single-center retrospective study, patients receiving short-term use of sodium nitroprusside demonstrated improved hemodynamic parameters as well as reduced all-cause mortality compared with patients who did not
receive nitroprusside although the latter was likely a result of increased chronic vasodilator use among patients transitioned from intravenous sodium nitroprusside.\textsuperscript{29}

In contrast to nitroglycerin and sodium nitroprusside, nesiritide has been the subject of several large randomized controlled trials in ADHF. In the Vasodilation in the Management of Acute CHF (VMAC) trial, which compared nitroglycerin and nesiritide in patients with ADHF and congestive symptoms, nesiritide conferred significant improvements in PCWP after several hours, but the differences had mostly dissipated by 48 hours.\textsuperscript{15} Some, but not all, subjective symptoms of congestion were initially improved with nesiritide compared with nitroglycerin, but were no different at study conclusion. A randomized controlled trial known as the Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (ASCEND) indicated that patients receiving nesiritide did no better or worse when the agent was added to standard therapies.\textsuperscript{30} Similarly, in the ROSE trial, adding low-dose nesiritide (0.005 mcg/kg/minute) to standard therapy had no impact on urine output or other clinical outcomes in patients with ADHF and renal impairment.\textsuperscript{18}

With respect to disadvantages, all three agents share hypotension as their most common adverse effect. In addition, tachyphylaxis often occurs with prolonged infusions of nitroglycerin (e.g., more than 12–72 hours) and less commonly with sodium nitroprusside. Sodium nitroprusside is associated with the unique risk of cyanide or thiocyanate toxicity in severe hepatic or renal dysfunction, although the risk is low in patients with ADHF given the lower doses and shorter durations commonly used in this setting. Its other disadvantages are of a practical nature; sodium nitroprusside commonly requires admission to an intensive care unit and placement of an arterial line for monitoring. Nesiritide is associated with rates of hypotension comparable to nitroglycerin and nitroprusside, but its long half-life may make it more problematic in patients with ADHF. In addition, given its lack of benefit compared with older agents, the cost of nesiritide precludes its use in most patients.

In the absence of symptomatic hypotension, intravenous
nitroglycerin, sodium nitroprusside, or nesiritide may be considered as an adjuvant to diuretic therapy for relief of dyspnea in patients admitted with ADHF, especially in those whose symptoms are potentially life threatening. In addition, their use should be preferentially considered over inotropes in patients with low cardiac output and normal or elevated blood pressure because these patients may benefit from improved ventricular performance as a result of reduced afterload. In the latter scenario, assessing invasive hemodynamic parameters with a PA catheter should be strongly considered before initiating vasodilators. Given the tenuous hemodynamic status of most patients with ADHF, nitroglycerin and sodium nitroprusside should be initiated at low doses and titrated no faster than every 5–15 minutes, depending on patient response. For nesiritide, bolus administration can be omitted in patients at risk of hypotension. Among the three agents, nitroglycerin may be more favorable for patients with marginal blood pressure because its mostly venous vasodilatory effects may not impart significant reductions in systemic arterial pressure. Sodium nitroprusside and, to a lesser degree, nesiritide, should be considered for patients with hypertension or those whose hemodynamics suggest systemic perfusion is likely to improve with reduced systemic vascular resistance. Given its minimal benefit over older agents and greater cost, nesiritide offers few practical advantages over nitroglycerin or sodium nitroprusside. As with the nitroprusside study described earlier, the ultimate goal should be to transition from intravenous to oral therapies, specifically a GDMT with similar hemodynamic properties.

**Inotropes**

Positive inotropic agents enhance tissue perfusion through increased myocardial contractility. Because of their effect on cardiac output, inotropes can also reverse the end-organ abnormalities that often complicate ADHF (e.g., cardiorenal syndrome). However, they do not impart a mortality benefit in ADHF and in fact may increase the risk of death as well as adverse effects. Dobutamine and milrinone are the two most commonly used agents in ADHF and will therefore be the focus of this chapter. Digoxin also has inotropic properties; however,
the role of digoxin is primarily for the management of chronic heart failure in the outpatient setting.

Although dobutamine and milrinone increase myocardial contractility, they differ in many aspects (summarized in Table 32.5). Dobutamine exerts its inotropic effects primarily by stimulating myocardial $\beta_1$ receptors. Some vasodilation may occur at lower doses because of dobutamine's effects on $\beta_2$ receptors in vascular smooth muscle, although this may be counteracted by corresponding improvements in cardiac output or its effects on peripheral $\alpha_1$ receptors at higher doses. Milrinone increases intracellular concentrations of cyclic adenosine monophosphate by inhibiting phosphodiesterase type 3, which confers enhanced contractility in myocardial tissue as well as relaxation of vascular smooth muscle in pulmonary and systemic arterial beds. As a result of these combined effects, milrinone is often called an inodilator.

Milrinone is often recommended in patients receiving chronic $\beta$-blockers because it bypasses $\beta$ receptors, although there is no evidence to suggest it confers a clinically meaningful benefit over dobutamine in this regard. In fact, some small studies suggest that chronic $\beta$-blocker use influences adrenergic receptor regulation, thereby preserving the potential for pharmacologic action by dobutamine. Studies are underway to address whether the pharmacologic activity of inotrope use in patients receiving $\beta$-blockers before admission depends on the inotrope selected and the $\beta$-blocker the patient had been receiving. Similarly, whether patients should continue receiving $\beta$-blockers in the setting of inotrope therapy also remains an area of controversy. Given the benefits of continuing $\beta$-blockers during an ADHF episode (as well as the worsened clinical outcomes associated with their discontinuation), some clinicians may prefer to continue $\beta$-blockers when initiating inotrope therapy.

Regarding pharmacokinetic properties, dobutamine has a fairly rapid onset of action and a short half-life; thus, it can be titrated rapidly depending on patient response. A notable exception occurs in patients who have been receiving dobutamine for extended periods (greater than 24 hours) because down-regulation of $\beta$-adrenergic receptors may
make rapid weaning difficult. In this latter scenario, therapy may need to be slowly tapered in a stepwise fashion depending on patient tolerance. Comparatively, milrinone has a slower onset of action and a longer half-life. Milrinone is primarily eliminated by renal clearance, and its half-life can be especially prolonged in patients with significant renal impairment. Consequently, it should be used with caution in patients with renal impairment and, if selected, initiated at lower doses and titrated more slowly.

As with vasodilators, few randomized controlled trials have assessed intravenous inotropes in ADHF. As previously discussed, when retrospectively compared with other vasoactive therapies in ADHERE, inotrope use portended an increase in mortality even when adjusted for differences in baseline characteristics. The arrhythmogenic potential of inotropic therapy serves as a pharmacologically plausible explanation for an increased risk of mortality, but this impact has not been confirmed in prospective studies. Only milrinone has been the subject of a large, prospective, randomized controlled trial; the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) showed that its routine use did not confer improved clinical outcomes and, instead, increased the risk of hypotension and atrial arrhythmias. Of note, patients with an indication for inotropic therapy (e.g., cardiogenic shock) were excluded from the trial; thus, it assessed only the routine use of milrinone in a diverse population with ADHF.

The decision to initiate inotrope therapy may be based on clinical features or invasive hemodynamic parameters. Whereas some clinicians prefer to initiate inotropes empirically when patients are refractory to other therapies or when unexpected responses occur (e.g., worsening renal function, ongoing congestion), others prefer invasive hemodynamic monitoring to confirm the presence of low cardiac output. As previously described, routine placement of a PA catheter does not improve outcomes in patients with ADHF, but its use is common when confirming the need for inotrope therapy and guiding dose titration.
Inotropes may improve cardiac output and therefore end-organ perfusion, but their potential benefit must be weighed against the risk of significant adverse effects. Both dobutamine and milrinone increase the sensitivity of the myocardium to catecholamines and other potentially arrhythmogenic stimuli. The commonly held notion that milrinone increases the risk of atrial arrhythmias whereas dobutamine increases the risk of ventricular arrhythmias has not been conclusively shown in the literature. Both agents likely increase the risk of arrhythmias to a comparable degree. With respect to distinguishing adverse effects, milrinone is associated with higher rates of hypotension as well as rare cases of thrombocytopenia.

cAMP = cyclic adenosine monophosphate; PDE3 = phosphodiesterase type 3.

*Bolus dosing listed in labeling but not used in practice

Inotropic agents are warranted as temporary or short-term therapy to maintain systemic perfusion and preserve end-organ function, or as a “bridge” to MCS or cardiac transplantation. For patients who are ineligible for advanced therapies, long-term inotropic therapy may be used as part of a palliative approach. As with vasodilators, inotrope administration requires frequent blood pressure monitoring as well as continuous monitoring for arrhythmias. Long-term use of intravenous...
inotropes for reasons other than those outlined previously is potentially harmful. Dobutamine can be titrated every 5–15 minutes depending on response, whereas milrinone should be titrated more slowly because of its slower onset of action and longer half-life (e.g., every 6–12 hours, or up to every 12 hours in patients with renal impairment). Tapering should occur gradually with both agents and be guided by patient response. Initiating agents that optimize ventricular loading conditions (e.g., ACE inhibitors or other oral vasodilators) may assist with inotrope weaning.

The decision regarding which inotrope to choose is often both clinician- and patient-dependent. An individual patient’s response is often unpredictable, and switching between therapies is common. In the setting of right ventricular (RV) failure, both therapies exert similar inotropic effects, although the vasodilating effects of milrinone may be helpful in patients with elevated pulmonary pressures. The systemic vasodilating effects of milrinone may be problematic in patients with low blood pressure. Therefore, dobutamine is usually preferred in patients with marginal blood pressure, although it, too, can lower blood pressure at low doses. Dobutamine may also be preferred in patients with renal impairment, although milrinone is not absolutely contraindicated. In fact, if renal impairment improves with enhanced tissue perfusion, higher doses may be required.

**Dopamine**

The role of dopamine as an adjunct to diuretics has been discussed previously. Its use may also be considered for patients in whom a decrease in blood pressure with dobutamine or milrinone is problematic because dopamine provides positive inotropic effects without systemic vasodilation; this feature may make it particularly useful in patients with mixed shock syndromes (e.g., combined cardiogenic and septic shock). However, its impact on α and β receptors can be highly variable in individual patients, making dose titration a challenge. Therefore, many clinicians prefer the combined use of dobutamine and a vasopressor with more predictable hemodynamic effects (e.g., norepinephrine) in this setting because titration of one or the other on
the basis of patient response is more straightforward.

MANAGING CHRONIC THERAPIES DURING AN ACUTE DECOMPENSATION

In the absence of hemodynamic instability or other contraindications, guidelines recommend that GDMT be continued.\textsuperscript{7} During hospitalization, every effort should be made to optimize standard heart failure therapy, although the timing of such is critical. β-Blockers should generally be continued during a hospitalization unless recent dose initiation or up-titration is thought to be the etiology of decompensation. In such cases, β-blockers may be dose reduced or temporarily held. Otherwise, discontinuation is discouraged because it has been associated with worse outcomes in both the prospective Beta-Blocker Continuation versus Interruption in Patients with Congestive Heart Failure Hospitalized for a Decompensation Episode (B-CONVINCED) trial and the retrospective OPTIMIZE-HF registry.\textsuperscript{32,33} For patients not receiving β-blockers, the Initiation Management Predischarge Process for Assessment of Carvedilol Therapy in Heart Failure (IMPACT-HF) trial showed that initiating β-blockers before discharge improved use at 90 days without increasing adverse effects.\textsuperscript{36} Guidelines recommend initiating β-blockers after optimal volume status has been achieved and after intravenous diuretics, vasodilators, and inotropic agents have been discontinued, although caution should be exercised in patients recently requiring inotropic therapy.\textsuperscript{7}

In the setting of renal dysfunction, ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists may also need to be temporarily held, especially with coexisting oliguria or hyperkalemia. Therapies that can cause worsening renal function (e.g., ACE inhibitors) should be initiated or titrated cautiously during aggressive diuresis. If an aldosterone antagonist is initiated in the setting of aggressive diuresis, serum potassium concentrations should be monitored closely as diuretic therapy is weaned or transitioned to a chronic oral regimen. Elevated serum digoxin concentrations may warrant dose reduction or temporary discontinuation, especially in the
setting of declining renal function. Permanent discontinuation is generally discouraged because an association between digoxin withdrawal and worsening heart failure is well documented.\textsuperscript{37,38} Digoxin discontinuation may be appropriate if serum concentrations cannot be maintained in a desirable range (0.5–0.9 ng/mL) because of fluctuating renal function.

TEMPORARY MCS

Many different temporary MCS modalities are available for patients with rapidly deteriorating ADHF or those refractory to pharmacologic support (Table 32.6). In general, indications for temporary MCS include cardiogenic shock with potentially recoverable cardiac function, hemodynamic support in high-risk patients undergoing cardiovascular procedures, or as a bridge to definitive therapy (e.g., durable MCS, cardiac transplantation).\textsuperscript{7,39} Three commonly used types of devices include the intra-aortic balloon pump (IABP), temporary ventricular assist device (VAD), and extracorporeal membrane oxygenation (Table 32.6). The role of extracorporeal membrane oxygenation is discussed separately (see page 656).

Patients for whom temporary MCS should be avoided include those with advanced peripheral vascular disease (particularly aortic disease for IABP and Impella), irreversible complications (e.g., anoxic brain injury after cardiac arrest), or patients who are otherwise ineligible for definitive therapies. The thrombotic risks of each device warrant systemic anticoagulation, although temporary IABP support without anticoagulation has been reported.\textsuperscript{40} Consequently, MCS should generally be avoided in patients with bleeding diathesis or other contraindications to anticoagulation. Other complications of temporary MCS include infection and vascular injury.

Intra-aortic Balloon Pump

An IABP consists of an elongated balloon affixed to the end of a catheter that is inserted into a large peripheral artery and advanced until the balloon rests in the descending aorta (between the aortic arch
and the splanchnic arteries). An IABP provides hemodynamic support by inflating during diastole, which enhances diastolic pressure and thus coronary perfusion, and by deflating during systole, which exerts a vacuum-like effect to reduce LV afterload, thereby improving cardiac output. According to the results of the second Intraaortic Balloon Pump in Cardiogenic Shock (IABP-SHOCK II) trial, the indiscriminant use of IABP in patients with cardiogenic shock has not been associated with improved outcomes. Thrombocytopenia may result from prolonged IABP use, which can be further worsened by concomitant anticoagulation therapy.

**Temporary VADs**
Temporary VADs include the percutaneously placed Impella (Abiomed, Danvers, MA) and TandemHeart (CardiacAssist, Pittsburgh, PA) devices and the surgically implanted CentriMag device (Thoratec Corp., Pleasanton, CA) (*Table 32.6*). Each provides continuous blood flow, although the Impella device facilitates flow by an axial mechanism, whereas the TandemHeart and the CentriMag both facilitate centrifugal flow. Unique complications of each device relate primarily to the implantation technique or the mechanism for facilitating blood flow. The axial flow mechanism of the Impella device confers an increased risk of hemolysis. Transeptal placement required for the TandemHeart device is associated with complications related to perforation and shunt formation. Finally, the CentriMag device is associated with risks related to the invasive surgical procedure required for its placement (e.g., tissue injury). A more detailed discussion of the hemodynamic complications of VADs, including RV failure, appears in the Durable MCS section.

---

**ADVANCED CARDIOVASCULAR THERAPIES**

Patients with end-stage heart failure may be eligible for durable MCS or cardiac transplantation. To be considered candidates for these advanced therapies, patients must undergo rigorous evaluation. Although cardiac transplantation remains the most optimal long-term
strategy for end-stage heart failure, limited donor availability as well as advances in durable MCS technology have led to sustained growth of VAD implantation.

CO = cardiac output; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

**Durable MCS**

Indications for durable MCS include patients being evaluated for cardiac transplantation (“bridge to candidacy”), those awaiting a suitable donor (“bridge to transplantation”), or as a permanent strategy (“destination therapy”). Relative contraindications to durable MCS include high perioperative risk, anatomic abnormalities expected to affect device function, irreversible pulmonary hypertension, comorbid conditions expected to limit survival, and inability to manage the device or pharmacologic therapy. Durable MCS can be distinguished as providing LV, RV, or biventricular support, although left ventricular assist device (LVAD) implantation is most commonly used in practice and will be the focus of this chapter.

The two LVADs currently approved in the United States are the
HeartMate II (Thoratec) and the HeartWare (Heart-Ware, Framingham, MA) ventricular assist systems. The HeartMate II is approved for both bridge to transplantation and destination therapy, whereas the HeartWare is currently approved only for bridge to transplantation. Both devices consist of an inflow cannula inserted into the apex of the left ventricle, a pumping unit, an outflow cannula inserted into the ascending aorta, and a subcutaneously placed driveline that connects the device to an external controller and power supply. The HeartMate II and the HeartWare are capable of producing up to 10 L/minute of continuous blood flow; blood flow is facilitated by axial flow in the HeartMate II and by centrifugal flow in the HeartWare.

Although a variety of parameters reported by the LVAD controller can help in troubleshooting complications, only pump speed can be adjusted directly. All LVADs are preload-dependent and afterload-sensitive; thus, the flow reported by the LVAD may indicate changes in hemodynamic status. Low blood flow may indicate hypovolemia or bleeding. High flows may represent systemic vasodilation, which could be an early sign of sepsis. Pulsatility index (PI) is a unique parameter that reflects the alterations in blood flow provided by contraction of the native left ventricle and negatively correlates with the degree of support required of the LVAD. Low PI may therefore represent low preload (e.g., hypovolemia or excess pump speed) or worsening LV function. High PI is uncommon except when LV function has improved. Finally, spikes in the power required by the LVAD to facilitate blood flow can indicate pump thrombosis.

A particularly challenging issue in a subset of patients with an LVAD is new-onset RV failure, often because of delayed resolution of pulmonary hypertension secondary to volume overload accompanied by an increase in venous return imparted by the LVAD. In addition, unloading of the left ventricle by the device may cause a leftward shift in the ventricular septum, which may further compromise RV geometry. Inotrope therapy can be used to improve RV contractility. The pulmonary vasodilation exerted by milrinone may be helpful in coexisting pulmonary hypertension, although systemic vasodilation may make dobutamine a better choice in select patients. Selective pulmonary vasodilators, such as phosphodiesterase type 5 inhibitors or
inhaled epoprostenol, may be helpful for reducing RV afterload. Aggressive volume removal and/or temporary reductions in LVAD speed may be required to alleviate excess RV preload. In refractory cases, temporary placement of an RV assist device or extracorporeal membrane oxygenation may be required.

The most significant challenge in patients with an LVAD is preventing device thrombosis while mitigating bleeding risk. Antithrombotic regimens often consist of both antiplatelet and anticoagulant therapy (usually aspirin and vitamin K antagonists). Antithrombotic management is complicated by acquired von Willebrand syndrome, which occurs as a result of shear stress imparted by the LVAD. In addition, bleeding at specific sites (e.g., intestinal mucosa) is thought to occur as a result of the loss of pulsatile flow with continuous-flow LVADs. Nonetheless, hemorrhagic complications may require a temporary decrease in anticoagulation therapy or cessation. Blood transfusion may be required for critical bleeding events, and leukocyte-reduced blood should be selected in patients undergoing bridge to transplantation to reduce the risk of allosensitization. Pump thrombosis is a potentially life-threatening complication requiring urgent evaluation. Consensus on the treatment of thrombosis is lacking; available modalities have included enhanced anti-platelet or anticoagulation therapy, thrombolytics, and, in severe cases, pump exchange or urgent transplantation.

Other complications of LVADs include infections and arrhythmias. Even mild infections thought to be localized to the driveline site or pump pocket (for HeartMate II) should be treated with aggressive empiric antimicrobial therapy to prevent seeding of the device. Patients with preexisting atrial fibrillation are treated similarly after LVAD implantation. Preexisting ventricular arrhythmias may not resolve after LVAD implantation and may in fact become worse for a time after surgery. If efforts to address hypovolemia (e.g., fluids, lower LVAD speed) are not effective for reducing arrhythmia burden, drug therapy (e.g., amiodarone, β-blockers) should be considered.

Cardiac Transplantation
The immediate postoperative treatment of cardiac transplant recipients is focused on bridging the patient to organ recovery, which can be delayed by prolonged ischemic time as well as reperfusion injury. Because of denervation of the implanted donor heart, inotropic and chronotropic therapy is especially important in the peri-operative period. A variety of inotropic agents (e.g., dobutamine, milrinone, epinephrine, isoproterenol) may be employed in this setting. Delays in myocardial recovery often impair the relationship between preload and stroke volume; thus, the donor heart may be especially reliant on chronotropy to maintain cardiac output. Heart rate targets in excess of 90 beats/minute are often advocated, and additional pharmacologic therapy (e.g., albuterol, theophylline) or temporary pacing may be required in patients whose heart rate remains low despite chronotropic therapy (e.g., isoproterenol).

Vasopressors may also be required to maintain peripheral perfusion (mean arterial pressure greater than 65 mm Hg). Preventing excess preload (central venous pressure less than 12 mm Hg) with the use of diuretics and venous vasodilators is necessary to prevent right heart overload. As with LVAD implantation, efforts to aggressively manage pulmonary hypertension are necessary to prevent acute right heart failure. Elevated pulmonary pressures that remain refractory to volume removal may require the use of selective pulmonary vasodilators.

After the immediate postoperative treatment of cardiac transplant recipients, achieving an appropriate degree of immunosuppression becomes the emphasis of drug therapy management. For patients with inadequate immunosuppression, the most common manifestation of acute graft rejection is ADHF, and patients are initially treated similarly to those with native heart failure. Other manifestations of acute graft rejection include myocardial ischemia, arrhythmias, and cardiac arrest, and each complication is acutely managed similarly in transplant recipients to those with native disease. Until graft dysfunction can be differentiated as being acute cellular rejection or antibody-mediated rejection in nature, aggressive corticosteroid use is often selected as an empiric immunosuppressive approach. Specific strategies for managing acute cellular rejection or antibody-mediated rejection differ
In addition to corticosteroids, therapeutic approaches for acute cellular rejection often include antithymocyte globulin, whereas consensus on managing antibody-mediated rejection is less clear. Therapeutic modalities for antibody-mediated rejection include corticosteroids, plasmapheresis, intravenous immunoglobulin G, and upstream anti-immunoglobulin therapies, such as rituximab and bortezomib.

PHARMACIST’S ROLE

Several studies have shown the positive role that pharmacists can play in managing patients with chronic heart failure. Given the growing emphasis on transitions of care and preventing heart failure readmissions, it is likely that many of these interventions will increasingly affect patients with ADHF. The PHARM (Pharmacist in Heart Failure Assessment Recommendation and Monitoring) study was the first randomized controlled trial to show the role of a clinical pharmacist in managing patients with chronic heart failure (n=192). Patients randomized to pharmacist intervention had a significant reduction in the combined primary end point, all-cause mortality and hospitalization or emergency department visit for heart failure (odds ratio 0.22, p=0.005), primarily because of a reduction in heart failure hospitalization. A more recent study showed higher rates of initiation or dose titration of select GDMTs with pharmacist-led 30-minute medication optimization compared with usual care. However, there was no difference in the primary end point, all-cause mortality, or heart failure related hospitalization. Multidisciplinary disease management programs, specialized heart failure clinics, and home-based interventions involving pharmacists have been associated with a wide range of benefits, including reduced heart failure readmissions and emergency department visits as well as improved adherence and symptoms. Pharmacists can provide a variety of services on the multidisciplinary team, including serving as experts on patient counseling. Finally, a recent systematic review of multidisciplinary teams involving a pharmacist showed reductions in all-cause and heart
failure hospitalizations. Lack of impact on mortality may have occurred because of limitations in study design (size, duration of follow-up). The American Heart Association recently published a statement describing transitional care interventions and outcomes and discussing implications and recommendations for research and clinical practice to enhance patient-centered outcomes. This statement acknowledges that of the transition of care programs for patients with heart failure (n=20), 75% used a collaborative, multidisciplinary team that included pharmacists.

CONCLUSION

Optimal management of ADHF requires pharmacists to effectively identify prognostic factors that allow stratification on the basis of potential lack of benefit or propensity for adverse events from ADHF therapies. Initial intravenous diuretic regimens should target prompt dyspnea relief, as should adjunctive strategies for managing refractoriness to diuretics. Select patients warrant intravenous vasodilator and/or inotropic therapy, and appropriate patient selection is critical for safe and effective use of these therapies. In addition to playing a key role in ensuring the optimal use of intravenous therapies, pharmacists should advocate for the appropriate use of GDMTs yet appreciate when referral for cardiac transplantation or MCS is necessary.

LEARNING OBJECTIVES

1. Review the pathophysiology and presentation of patients with an acute coronary syndrome (ACS).
2. Describe the role of anti-ischemic therapy in the management of ACS.
3. Compare and contrast the antiplatelets and anticoagulants routinely used in ACS.

INTRODUCTION

Cardiovascular (CV) disease is the leading cause of death in the United States. An acute coronary syndrome (ACS), including unstable angina and myocardial infarction (MI), are the most common cause of CV death. An estimated 15.5 million Americans older than 20 years have coronary artery disease. The overall prevalence of MI is 2.8% in U.S. adults (4.0% in men vs. 1.8% in women). The complexity of the disease combined with the rapidly evolving literature can be overwhelming to practitioners. The primary purpose of this chapter is to discuss important considerations in disease assessment and medication evaluation in ACS management.
Mechanism of Plaque Rupture and Thrombus Formation
An ACS event begins with the rupture of an unstable coronary atherosclerotic plaque. This rupture exposes the plaque contents to the circulating blood. The thrombogenic contents, including collagen and tissue factor, promote platelet adhesion and activation. Platelet-derived vaso-active substances such as adenosine diphosphate (ADP) and thromboxane $A_2$ (TXA$_2$) promote additional platelet activation and vasoconstriction. Platelet activation also results in a conformational change to the glycoprotein IIb/IIIa surface receptor. Platelet aggregation involves the crosslinking of activated platelets through the surface glycoprotein IIb/IIIa receptor with fibrinogen. Simultaneously, the extrinsic clotting cascade is activated, leading to the production of thrombin (factor IIa) and ultimately fibrin (factor Ia).

Disease Assessment
Patients with suspected ACS should have a comprehensive workup that evaluates chest pain history, cardiac markers, and electrocardiographic (ECG) findings.

Risk Scoring
Several risk assessment scores have been developed and validated to encourage the timely diagnosis and treatment of patients presenting with an ACS. A score can easily and objectively risk-stratify patients with non-specific ischemic symptoms. Most clinical prediction algorithms use a combination of clinical history, physical examination, cardiac markers, and ECG. These scoring systems are not designed to assess whether a patient’s signs and symptoms are caused by ACS, but to estimate their in-hospital, 6-month, and 3-year mortality. Three common examples of validated risk assessment scores include the Thrombolysis In Myocardial Infarction (TIMI), Platelet Glycoprotein IIb-IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT), and Global Registry of Acute Coronary Events
(GRACE) scores (Table 33.1). The TIMI score uses seven variables, all of which carry the same magnitude of risk, to predict death, MI, or target vessel revascularization at 14 days. The PURSUIT score uses five variables to predict short-term outcomes at 30 days, whereas the GRACE score uses eight variables to predict in-hospital mortality and MI. An updated GRACE score (GRACE 2.0) has been created to simplify and strengthen the predictability of the clinical tool (substitutes Killip class for diuretic use, and serum creatinine with a history of renal dysfunction). Patients with an ACS can be assigned a low, moderate, or high-risk score to aid in their prognosis and care. No prediction tool has been proven superior to another, so many clinicians use the TIMI risk score for ease and convenience.

Severity  7–10 on a 10-point scale
Temporal  > 20 min

**Chest Pain Story**

Chest pain is the most common symptom reported in patients experiencing an ACS event.\(^1,2\) Because chest pain is subjective, the PQRST [pain characteristics in low back pain syndrome] pain assessment method can be used to accurately and comprehensively acquire the classic characteristics of the event (Table 33.2). The chest pain associated with an ACS event is not typically precipitated by exertion and often occurs at rest. In addition, rest or organic nitrate administration does not typically result in the palliation of ACS chest pain. Patients may qualify the chest pain as a stabbing and/or crushing pain. This pain typically begins at the anterior midline and may radiate to either arm or shoulder, the back, or the lower jaw. Pain reported below the lower jaw and above the umbilicus is possible during or immediately after an ACS event. Patients often report the pain as severe, equivalent to a score of 7/10. Finally, the absence of pain relief from rest and organic nitrates usually results in episodes lasting more than 20 minutes. Although these characteristics describe the classic chest pain symptoms, women, patients with diabetes, and older adult patients may have an atypical presentation. Other associated symptoms that may occur during an ACS event include diaphoresis, shortness of breath, distress, nausea, and vomiting.

**Cardiac Markers**

Patients with severe or prolonged myocardial ischemia will develop
myocardial necrosis. Myocardial infarction is associated with elevations in both specific and non-specific cardiac markers. These biochemical markers are important in the evaluation, diagnosis, and triage of patients with chest pain (Table 33.3). Accurate interpretation of clinically relevant biomarkers requires an understanding of both their biology and their kinetics. Creatine kinase (CK) is composed of three isoenzymes: CK-MB, CK-MM, and CKBB. Although CK is found in many tissues throughout the body, the distribution of the isoenzymes varies significantly. About 20% of total CK in the cardiac muscle is CK-MB compared with only 2%–5% of total CK in the skeletal muscle. The total CK is not cardiac-specific, and elevations can be observed in patients with cardiac, skeletal, and cerebral injuries. The CK-MB is the most cardiac-specific isoenzyme because of its relatively low distribution in non-cardiac tissues. Elevations in both total CK and CK-MB can be observed after cardiac and non-cardiac injuries. The CK-MB/total CK ratio or CK-MB relative index can be used to differentiate cardiac disease from non-cardiac disease. A CK-MB greater than 5% of the total CK is suggestive of an ACS event. The CK isoenzymes share a similar kinetic pattern including an initial rise in 4–9 hours, a peak in 24 hours, and normalization in 24–48 hours. Because of advances in troponin assays, CK and CK-MB are no longer recommended in the diagnosis of ACS. If measured in this setting, several CK-MB and total CK measurements should be considered to avoid a false-negative result early (within 0–4 hours) after the onset of chest pain. False-positive results can be observed in patients with muscle disorders, chronic renal failure, hypothyroidism, pulmonary edema, and congestive heart failure.

| Table 33.3 | Kinetic Profiles of Cardiac Biomarkers<sup>8–10</sup> |
Myoglobin is a small protein found in high concentrations in both cardiac and skeletal muscles. Although non-specific for cardiac disease, the kinetic profile of myoglobin aids in its clinical utility. Myoglobin is released within 1–2 hours after muscle injury. A peak myoglobin concentration is achieved within 4–12 hours and is rapidly cleared from the blood within 24 hours. Myoglobin has a high negative predictive value and poor specificity, making it more clinically useful to rule out ACS, rather than confirming the diagnosis.8

Troponin is a three-protein complex (troponin C [TnC], troponin T [TnT], and troponin I [TnI]) used in the contractile apparatus of muscles. Although cardiac and skeletal muscles both contain TnT and TnI, the amino acid sequence is unique enough to differentiate cardiac troponin (cTnC, cTnT, and cTnI) from skeletal troponin. The troponin subunits share a similar kinetic pattern including an initial rise in 4–9 hours, a peak in 12–24 hours, and normalization within 14 days. Several cTnT or cTnI measurements should be considered to avoid a false-negative result early (within 0–4 hours) after the onset of chest pain. Troponin is routinely measured at baseline, 8 hours, and 16 hours to assist in the diagnosis of ACS. The European Society of Cardiology (ESC) and the American College of Cardiology (ACC) Joint Committee have defined MI as an elevated cardiac troponin above the 99th
percentile of the healthy reference population.\textsuperscript{9}

Troponin has several ideal features, including biologic, kinetic, and prognostic, which makes it a valuable test in the clinical assessment of ACS. First, cTnT and cTnl is found in relatively high concentrations within the myocardium and is absent within non-cardiac tissue and in the blood of healthy individuals. Second, troponin is released rapidly after myocardial injury, aiding in a timely diagnosis. Third, the magnitude of troponin elevation has been correlated with the risk of death after an ACS event. In addition, troponin may be helpful in identifying an optimal management strategy. Finally, the technology to measure cTnT and cTnl has seen several clinically significant advances. The likelihood of a false-positive and negative result with troponin is less than with myoglobin and CK-MB. Most assays are highly sensitive and specific, and point-of-care troponin testing can produce a qualitative and quantitative result in about 15 minutes. False positives can be observed in patients with other cardiac disease states including advanced heart failure, myocarditis, and pericarditis. Some non-cardiac disease states may also result in a false-positive troponin including chronic obstructive pulmonary disease, pulmonary embolism, and chronic renal failure. In renal failure, an elevated cTnT is observed more often than is cTnl because of cTnT’s instability in the serum and higher clearance during dialysis.\textsuperscript{10}

**ECG Findings**
Myocardial ischemia and infarction can be detected using a 12-lead ECG. The ECG can help clinicians understand the presence, extent, and severity of ischemia. Ischemic episodes can be observed on the ECG within minutes of the index event. An ECG should be ordered and interpreted within 10 minutes on arrival to an emergency department.\textsuperscript{1} Typical ECG findings indicative of ischemia include T-wave inversion, ST-segment depression, and ST-segment elevation. Comparison of a baseline ECG can be helpful in assessing whether ischemic changes are new or old. Changes within specific groupings of ECG leads can suggest the location of the occluded coronary lesion (Table 33.4).\textsuperscript{11}

</table>

Patients with unstable angina and non-ST-segment elevation (NSTE) may present with T-wave inversion and ST-segment depression, and in some instances, the ECG may remain normal. However, the diagnosis of ST-segment elevation myocardial infarction (STEMI) requires the presence of ST-segment elevation. The ESC and ACC guidelines have defined the amplitude change needed for ST-segment elevation as 0.2 mV in men and 0.15 mV in women (leads $V_2$ and $V_3$) or 0.1 mV in any other ECG lead. Pathologic Q waves may also occur several hours to days after an MI. A Q wave appears when electrical activity is absent and rarely disappears despite aggressive pharmacologic and reperfusion strategies.\textsuperscript{1,2,11}

The presence of a left bundle branch block (LBBB), which may occur in 7% of patients, makes interpreting the ECG more difficult during periods of ischemia.\textsuperscript{12} The baseline ST-segment and T-wave morphology seen with LBBB can mask or mimic the ECG findings during an infarction. A new LBBB is always pathological and may be a sign of MI. The Sgarbossa criteria can be used in patients with a new LBBB and suggestion of an infarct. A Sgarbossa score of 3 or greater
has a specificity of 90% for detecting an infarct.\textsuperscript{13}

ROLE OF GUIDELINES

Guidelines
Several groups have written guidelines for the management of ACS, including the ACC and the American Heart Association (AHA). The 2013 STEMI and 2014 NSTE ACC/AHA guidelines use both a class and a level system to describe the magnitude and strength of the recommendation. A class I recommendation signifies that the potential benefits outweigh any perceived risks, whereas a class III recommendation implies that the procedure or treatment has no benefit or may be harmful. A level A recommendation is derived from several randomized controlled trials or a meta-analysis, whereas a level C recommendation is based on case studies or expert opinion.\textsuperscript{1,2}

Other expert groups have either written or endorsed guidelines (e.g., Society for Cardiovascular Angiography and Interventions, Society of Thoracic Surgeons, ESC). Although other consensus statements and guidelines exist, the ACC/AHA guidelines are considered the gold standard for preventing ACS and treating patients with ACS in the United States.

Core Measures
The ACS core measures represent standards of care that have a clear morbidity and mortality benefit. The acute MI set consists of seven measures (Table 33.5) involving care at admission and on discharge. This quality initiative allows patients, accrediting agencies, and reimbursement groups to evaluate institutions on the basis of performance and quality.\textsuperscript{15}

ANTI-ISCHEMIC THERAPY

Oxygen
Historically, oxygen has routinely been administered to all patients with suspected ACS on arrival to the hospital. Evidence for this practice is seeded by weak studies performed in non-human models. Oxygen administration has become routine practice because of the hypothesis that supplemental oxygen improves coronary perfusion pressures and reduces myocardial necrosis. However, hyperoxia appears to have some detrimental effects such as reflex vasoconstriction, increased peripheral and systemic vascular resistance, and cardiotoxicity from oxygen free radicals. Consequently, guidelines now recommend supplemental oxygen during the first 6 hours after arrival in patients with respiratory distress, hypoxic signs and symptoms, or an oxygen saturation less than 90% (American College of Cardiology Foundation [ACCF]/AHA) NSTE class I, level of evidence [LOE] C and STEMI class I, LOE B).

ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; LVSD = left ventricular systolic dysfunction; MI = myocardial infarction; PCI = percutaneous coronary intervention.

**Nitrates**

The selection and role of nitrate administration in the management of ACS is highly dependent on the formulation’s pharmacokinetic profiles. Nitroglycerin forms free radical nitric oxide, which activates guanylate cyclase, resulting in an increase of guanosine 3'5'-monophosphate (cyclic GMP) resulting in smooth muscle vasodilation. In general, nitrates should be considered for symptomatic relief because they have no long-term mortality benefit.17,18

Sublingual nitrates are recommended for symptomatic relief in the management of acute chest pain. However, patients experiencing an ACS event may not receive any symptomatic relief from sublingual administration. Most patients with acute chest pain will receive up to 3 sublingual nitroglycerin 0.4-mg tablets administrated 5 minutes apart (ACCF/AHA NSTE and STEMI class I, LOE C).1,2 The sublingual tablets are quickly dissolved and absorbed through buccal absorption with a mean Cmax (maximum concentration) of 6–7 minutes. In the acute setting, nitrates dilate both normal and atherosclerotic coronary arteries to enhance coronary blood flow to the myocardium. In vessels that are almost 100% occluded, additional vasodilation likely has little to no benefit.

In the setting of acute chest pain, intravenous nitroglycerin administration may provide additional benefit by decreasing preload and left ventricular end-diastolic volume. Ultimately, these hemodynamic changes provide a reduction in myocardial oxygen demand. Continued use of intravenous nitroglycerin typically occurs in patients who have had an ACS event with ongoing hypertension or symptoms of heart failure (ACCF/AHA NSTE class I, LOE B and STEMI class I, LOE
Extreme caution should be taken in patients who are normotensive, and intravenous nitroglycerin should be avoided in patients with hypotension (systolic blood pressure less than 90 mm Hg). Nitroglycerin should also be avoided in patients with ventricular dysfunction who are preload-dependent. Typically, intravenous nitroglycerin is initiated at 5 mcg/minute with dosage adjustments of 5 to 10 mcg/minute up to a maximum dose of 200 mcg/minute. Tolerance can develop with intravenous nitroglycerin within 12 to 24 hours. Clinicians should reassess the need for and effectiveness of intravenous nitroglycerin every 6–12 hours.

β-Blockers

β-Blockers are routinely used in both acute and chronic management of ACS. β-Adrenergic inhibitors reduce blood pressure, heart rate, and contractility, which ultimately reduces cardiac demand. Inhibition of norepinephrine on cardiac tissue reduces the need for oxygen-rich blood supply. In general, β-blockers should be selected on the basis of their selectivity and binding properties. Patients experiencing an ACS event should receive a β₁-selective agent without intrinsic sympathomimetic activity.

β-Blockers have been proven safe and effective in most patients with ACS. β-Blockers should be initiated within the first 24 hours in patients without heart failure, low-output state, and cardiogenic shock (ACCF/AHA NSTE class I, LOE A and STEMI class I, LOE B). The use of β-blockers in patients with other contraindications including a PR interval greater than 0.24 second, second- or third-degree heart block, or severe airway disease should also be avoided. The use of intravenous β-blockers should be avoided in patients in shock or with risk factors for cardiogenic shock, including age older than 70 years, heart rate greater than 110 beats/minute or less than 60 beats/minute, systolic blood pressure less than 120 mm Hg, and late presentation (ACCF/AHA NSTE class III, LOE B and STEMI class IIa, LOE B). Patients with stable heart failure and an ejection fraction less than 40% should be initiated on metoprolol succinate, bisoprolol, or carvedilol
before discharge. These agents have a proven mortality benefit in patients with systolic heart failure.

Several early trials showed benefits with the use of early β-blockers on infarct size, recurrent chest pain, reinfarction, and death. More recently, the Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) study was designed to evaluate the use of β-blockers in the management of acute MI. Patients presenting with STEMI were randomized to receive intravenous metoprolol (n=22,929) or placebo (n=22,923). Patients randomized to receive β-blocker therapy were initiated on intravenous metoprolol (up to 15 mg) and then converted to oral metoprolol succinate (up to 200 mg daily). The use of early β-blocker therapy resulted in significantly fewer reinfarctions (2.0% vs. 2.5%; p=0.001) and ventricular fibrillation events (2.5% vs. 3.5%; p=0.001) but increased the risk of cardiogenic shock (5.0% vs. 3.9%; p<0.00001). The risks of β-blocker use were highest during hospital admission days 0–1, and the benefits of β-blocker therapy were seen more gradually over time. These data analyses influenced the core measures to eliminate the β-blocker requirement at admission and support the use of β-blockers; then, the hemodynamic status was stable.

Calcium Channel Blockers
Calcium channel blockers provide vasodilation, a reduction in heart rate, and a reduction in myocardial contractility. The calcium channel blockers need to be considered by class. Although the dihydropyridines provide vasodilation and a reduction in blood pressure, the class may cause reflex tachycardia. Clinically, it would be prudent to administer concomitant β-blockers with dihydropyridine calcium channel blockers, especially nifedipine. The non-dihydropyridine calcium channel blockers decrease blood pressure, heart rate, and myocardial contractility. Clinically, the non-dihydropyridine calcium channel blockers should be avoided in patients with pulmonary edema or heart failure because of their negative inotropic effects.

Non-dihydropyridine calcium channel blockers can be used in
patients with persistent chest pain and a contraindication to β-blockers (ACCF/AHA NSTE class I, LOE B).\textsuperscript{1,2} Patients with significant left ventricular dysfunction, PR interval greater than 0.24 second, or second- or third-degree heart block should not receive a non-dihydropyridine calcium channel blocker such as verapamil or diltiazem. Calcium channel blockers may be beneficial in patients with chest pain secondary to coronary artery spasm (ACCF/AHA NSTE class I, LOE C).\textsuperscript{2} The ACCF/AHA guidelines make no formal recommendations regarding the use of calcium channel blockers in the management of STEMI.\textsuperscript{1}

Verapamil and diltiazem have provided reductions in reinfarction rates in patients without left ventricular dys-function in some trials. The DAVIT-II (Danish Verapamil Infarction Trial) found no difference in mortality in patients receiving verapamil compared with placebo after 18 months (11.1\% vs. 13.8\%; \(p=0.11\)).\textsuperscript{25} Reinfarction rates were lower with verapamil (11.0\%) than with placebo (13.2\%; \(p=0.04\)). In a subgroup analysis, verapamil was associated with lower mortality in patients without heart failure (7.7\% vs. 11.8\%; \(p=0.02\)). Diltiazem was studied in patients who had experienced a non–Q-wave MI.\textsuperscript{26} No difference in overall mortality was seen between diltiazem and placebo (3.1\% vs. 3.8\%; \(p=0.373\)). Reinfarction rates were lower with diltiazem (5.2\%) than with placebo (9.3\%; \(p=0.0297\)).

**Morphine**

Opioid analgesics are used for their potent analgesic and anxiolytic properties. In addition, opioid analgesics provide modest reductions in vascular resistance, heart rate, and systolic blood pressure. These hemodynamic properties are beneficial in patients experiencing cardiac chest pain.\textsuperscript{27–29}

In patients with chest pain despite antianginal therapy, intravenous morphine sulfate 2–4 mg may be administered (ACCF/AHA NSTE class IIb, LOE B and STEMI class I, LOE C).\textsuperscript{1,2} Morphine administration can be repeated every 5–15 minutes for persistent chest pain with blood pressure monitoring. The use of morphine should not preclude the use of other anti-ischemic agents aimed at increasing coronary supply and
reducing demand. The most critical adverse effects with morphine are hypotension and respiratory depression. Naloxone 0.4–2.0 mg should be readily available to prevent respiratory and circulatory depression.

ANTITHROMBOTIC THERAPY

The thrombotic nature of most ACS events makes timely and appropriate antithrombotic therapy critical to optimal treatment of these patients. Antithrombotic therapy is composed of antiplatelet and anticoagulant agents. Although platelets dominate the pathophysiological process in arterial thrombosis, the central role of thrombin in both platelet activation and coagulation makes both types of therapy necessary in the patient with ACS.\(^\text{30,31}\)

Of note, not all agents have been investigated across the spectrum of ACS, or in different management strategies. The choice of antiplatelet and anticoagulant therapy, as well as dose, may change depending on the patient’s ACS diagnosis and management approach (Table 33.6).

Antiplatelet Therapy

Aspirin
Aspirin has been the cornerstone of antiplatelet therapy in patients with ACS for several decades. Early and maintained aspirin therapy has shown the ability to reduce death and MI in patients across the spectrum of ACS.\(^\text{32}\) Although there is little controversy about using an initial dose of 162–325 mg chewed and swallowed for rapid platelet inhibition, even for patients on chronic aspirin, the daily dose of aspirin after the initial loading dose use of aspirin remains an issue of discussion.

Aspirin acetylates a specific hydroxyl group of serine 530 on cyclooxygenase (COX)-1 enzyme, which inhibits the binding of arachidonic acid and subsequent creation of TXA\(_2\) in platelets and prostacyclin (PGI\(_2\)) in endothelial cells.\(^\text{33}\) Aspirin-induced inhibition of
TXA$_2$ and PGI$_2$ produces opposing effects on hemostasis. In platelets, TXA$_2$ stimulates the platelet release reaction, causing platelet aggregation as well as producing potent vasoconstriction. In contrast, vascular endothelium-derived PGI$_2$ serves as a protective factor by preventing platelet activation and providing vascular smooth muscle dilation. Aspirin’s ability to inhibit platelet aggregation, even with a short half-life (15–20 minutes), is because of the irreversible binding to the COX-1 enzyme in platelets, whereas vascular endothelial cells have the ability to regenerate new COX and sustain normal function. A single dose of 100 mg will eliminate TXA$_2$ production. Doses below 100 mg result in dose-dependent effects on TXA$_2$ and COX inhibition, with daily dosing resulting in a cumulative effect.

The Antithrombotic Trialists’ Collaboration showed the protective effects of aspirin in patients with a high risk of vascular events. Aspirin provided a significant reduction in nonfatal MI, nonfatal stroke, or vascular death in patients presenting with unstable angina and acute MI. Aspirin doses of 75–1,500 mg daily were evaluated with no significant difference in efficacy between lower doses (75–150 mg), medium doses (160–325 mg), and higher doses (500–1,500 mg). Higher doses were associated with increased GI irritation. In the Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events–Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT–OASIS 7) trial, aspirin doses of 300–325 mg daily provided no efficacy benefit over doses of 75–100 mg daily, with significantly more GI bleeding with the higher-dose regimen. The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial showed an aspirin dose-dependent increase in major bleeds in
clopidogrel plus aspirin therapy with a 4.9% rate in daily aspirin doses greater than 200 mg.\textsuperscript{39} Low doses of aspirin may selectively bind platelet COX, resulting in the inhibition of TXA\textsubscript{2} with the advantage of leaving vascular endothelial PGI\textsubscript{2} production intact.\textsuperscript{35,36} Although the current ACC/AHA guidelines provide a class I, LOE A recommendation for post-loading doses of 81–325 mg daily, a daily maintenance dose of 81 mg daily is considered reasonable (class IIa, LOE B).\textsuperscript{1,2}

**P2Y\textsubscript{12} Inhibitors**

Currently, four P2Y\textsubscript{12} inhibitors are available for use in patients with ACS.\textsuperscript{40–43} Clopidogrel is an orally administered, selective, irreversible inhibitor of the P2Y\textsubscript{12} receptor. Similar to its predecessor ticlopidine, clopidogrel is a thienopyridine prodrug that requires hepatic activation. The active metabolite of clopidogrel is responsible for binding to the P2Y\textsubscript{12} receptor leading to platelet inhibition. The active metabolite of clopidogrel has a reactive thiol group, which forms a disulfide bond with the cysteine residues on the P2Y\textsubscript{12} receptor, creating an irreversible inhibition of the P2Y\textsubscript{12} receptor for the life of the platelet.\textsuperscript{44,45} This ultimately leads to prevention of ADP-mediated platelet activation and aggregation. Because of this irreversible binding, it is recommended that clopidogrel therapy be withheld for 5 days before coronary artery bypass grafting (CABG) or other major surgery to allow time for new uninhibited platelets to be created.\textsuperscript{1,2}

Clopidogrel has been extensively studied in patients with ACS. In the CURE trial, patients with NSTE ACS receiving a 300-mg loading dose of clopidogrel followed by 75 mg daily had a significant reduction in CV death, MI, and stroke compared with those receiving aspirin alone (9.3\% vs. 11.4\%; p<0.001).\textsuperscript{39} The results of the CURE trial created a paradigm change by making dual anti-platelet therapy (DAPT) the standard of care in patients with NSTE ACS. Data analyses from the COMMIT and the Clopidogrel as Adjunctive Reperfusion Therapy-Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI 28) showed similar benefits of DAPT with aspirin and clopidogrel over the use of aspirin alone in patients presenting with STEMI. Using DAPT with
clopidogrel typically comes at the risk of a statistically significant absolute increase in major bleeding of about 1%, but without a significant increase in life-threatening bleeding, intracranial hemorrhage (ICH), or fatal bleeding.\textsuperscript{39,46,47} Therefore, clopidogrel is currently the only P2Y\textsubscript{12} inhibitor with evidence across the spectrum of ACS (NSTE ACS and STEMI) and can be used regardless of the management strategy selected (ischemia-driven, early invasive, fibrinolysis, or primary percutaneous coronary intervention [PCI]).\textsuperscript{1,2} Despite the wealth of data and experience using clopidogrel as part of DAPT, three main controversies raise questions about the widespread use of clopidogrel in all patients with ACS. These issues include concern about drug interactions, variability in the antiplatelet response, and cytochrome P450 (CYP) 2C19 polymorphisms.

Clopidogrel requires a two-step activation by several CYP enzymes (2C\textsubscript{19}, 3A\textsubscript{4}, 1A\textsubscript{2}, 2B\textsubscript{6}), with more than 50% of metabolism being because of CYP2C\textsubscript{19}.\textsuperscript{45,48} Because of the significant role of CYP219 metabolism in creating the active clopidogrel metabolite, drug interactions that reduce the amount of active clopidogrel have become an issue of concern. Although the clopidogrel prescribing information makes a general statement about the potential for inhibitors of CYP2C\textsubscript{19} to reduce concentrations in the active metabolite and a reduction in platelet inhibition, most of the controversy surrounds the concomitant use of proton pump inhibitors (PPIs). Package labeling recommends avoiding the concomitant use of clopidogrel with omeprazole and esomeprazole and suggests considering less potent CYP2C\textsubscript{19} inhibitor PPIs such as dexlansoprazole, lansoprazole, and pantoprazole that have had less impact on platelet function in pharmacodynamic studies.\textsuperscript{49} In a pharmacodynamic evaluation, there was a significant increase in platelet reactivity with 7 days of clopidogrel with omeprazole compared with clopidogrel alone, suggesting less active clopidogrel when combined with a PPI.\textsuperscript{50} This concern grew when several observational cohort trials also suggested worse clinical outcomes in patients receiving a PPI with clopidogrel.\textsuperscript{51,52} Despite complex matching and propensity scoring in these analysis, they are unable to account for the potential that
patients receiving PPIs may be sicker patients. In contrast, a post hoc analysis of prospectively designed studies showed no difference in adverse clinical outcomes in patients receiving PPIs with clopidogrel compared with those receiving clopidogrel alone. The only prospectively designed study to answer this question was discontinued early because of funding issues. Despite this flaw, there was no signal of an increase in the risk of CV events in patients receiving clopidogrel and omeprazole compared with clopidogrel alone (p=0.98). Therefore, the clinical relevance of the PPI and clopidogrel drug interaction may be limited.

Probably the most significant area of controversy surrounding clopidogrel use is the variability in platelet inhibition. Although several different testing methods and definitions have been used, data analyses show that up to 40% of patients (5%–44%) do not obtain adequate platelet inhibition, which has been termed nonresponsiveness. Several studies have shown that patients who are identified as nonresponsive to clopidogrel have significantly more adverse CV outcomes than those who achieve an adequate response. Although patients who have an adequate antiplatelet response to clopidogrel seem to rarely have adverse CV events, and those who are nonresponders are more likely to have events, most patients classified as nonresponders also do not have CV events. Therefore, platelet function testing has a much stronger negative than positive predictive value (predicting who will not have events compared with predicting those who will). Nevertheless, platelet function testing in existing studies and practice does not follow these results and tries to decide how to manage nonresponders. Current trials have not provided guidance on the utility of a tailored strategy with antiplatelet selection (switching to prasugrel) or dosing (clopidogrel 150 mg instead of 75 mg daily) in patients determined to be nonresponsive on the basis of platelet reactivity testing results. Of note, these studies have only been conducted in patients undergoing elective PCI or low-risk ACS; higher-risk ACS patients who have more adverse CV events would be expected to have the most benefit from alternative P2Y\textsubscript{12} strategies.

Clopidogrel’s reliance on CYP2C19 for most of its metabolism to the
active compound has made polymorphism of this enzyme a suspected culprit in the genesis of clopidogrel nonresponsiveness. Although more than 20 genetic polymorphisms have been identified for CYP2C19, the most significant include CYP2C19*2 and CYP2C19*3 because these polymorphisms result in the loss of the functional allele.\textsuperscript{40,45} Studies have shown a reduction in the formation of clopidogrel's active metabolite-based CYP2C19 genotype. Although some studies have also shown an increase in CV events in patients with CYP2C19 polymorphisms, not all studies confirm these findings.\textsuperscript{61} Studies have tried to correlate the antiplatelet effect of clopidogrel and CYP2C19 polymorphisms. Results from these studies have shown that identifying CYP2C19 status explains only 12\%–15\% of the variability in clopidogrel response.\textsuperscript{62,63} Therefore, many patients with “wild-type” CYP2C19 will still not achieve adequate antiplatelet response to clopidogrel. At this time, genetic testing is not the answer to explaining poor antiplatelet response to clopidogrel therapy.

Prasugrel was developed to overcome some of the limitations and concerns with clopidogrel. Although prasugrel is a thienopyridine similar to ticlopidine and clopidogrel that requires hepatic activation, the conversion of prasugrel to its active compound requires only a single step with several CYP enzymes able to contribute. Therefore, the formation of prasugrel to its active compound is faster and more efficient than that of clopidogrel. No significant CYP drug interactions have been reported with prasugrel.\textsuperscript{64} In pharmacodynamic studies, prasugrel provides both faster and more potent platelet inhibition than clopidogrel.\textsuperscript{65–67} Pharmacodynamic data analyses show that patients found to be nonresponders to clopidogrel consistently become responders when given prasugrel.\textsuperscript{65–67} Because prasugrel also forms an irreversible disulfide bond with the P2Y\textsubscript{12} receptor and the level of platelet inhibition is greater, a 7-day hold is recommended for patients needing CABG or other major surgery.\textsuperscript{1,2}

The efficacy and safety of prasugrel was assessed in patients with NSTE ACS and STEMI undergoing PCI in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel Thrombolysis In Myocardial Infarction 38 (TRITON-TIMI
The regimen of a prasugrel loading dose of 60 mg followed by 10 mg daily provided a significant reduction in CV death, MI, and stroke (9.9% vs. 12.1%; p<0.001) as well as stent thrombosis (1.1% vs. 2.4%; p<0.001) compared with a 300-mg loading dose of clopidogrel followed by 75 mg daily. Prasugrel had an exaggerated benefit in patients with diabetes mellitus, who typically have higher platelet reactivity. Although patients without diabetes mellitus had a significant 14% relative reduction in the primary end point with the use of prasugrel over clopidogrel (p=0.02), patients with diabetes mellitus had a significant 30% relative reduction with the use of prasugrel (p<0.001). Although using a 300-mg loading dose of clopidogrel could be considered a criticism of the trial, pharmacodynamic data analyses show that this regimen of prasugrel still provides significantly better platelet inhibition than does double-dose clopidogrel (600-mg load and 150 mg daily).

Because of the more potent platelet inhibition of prasugrel compared with clopidogrel, major bleeding was significantly higher for patients receiving prasugrel compared with clopidogrel (2.4% vs. 1.8%; p<0.001). Although the absolute numbers were low, there was also an increase in the incidence of life-threatening (0.9% vs. 1.4%; p=0.01) and fatal (0.1% vs. 0.4%; p=0.002) bleeding with the use of prasugrel. To identify which patients were at higher risk of bleeding with prasugrel, a post hoc analysis was performed on the TRITON-TIMI 38 database. In this analysis, patients with weight less than 60 kg, age older than 75 years, or a history of transient ischemic attack (TIA) or stroke had higher rates of bleeding using prasugrel relative to clopidogrel than did the overall study group. Therefore, when considering the efficacy and safety together as a net clinical benefit (death, MI, stroke, and major bleeding), the optimal patient for receiving prasugrel would weigh more than 60 kg, be younger than 75 years, and have no history of TIA or stroke. This patient population made up 80% of patients in the TRITON-TIMI 38 trial, and these patients had a 20% significant benefit of receiving prasugrel over clopidogrel (10.2% vs. 12.5%; p<0.001). Prasugrel is generally not recommended in patients older than 75 years because of excess fatal bleeding, except in patients presenting with...
diabetes mellitus or STEMI. Despite the higher risk of bleeding, the profound benefit of prasugrel compared with clopidogrel in patients with diabetes mellitus or STEMI outweighs this risk. Patients weighing less than 60 kg are recommended to receive a maintenance dose of 5 mg daily instead of the typical 10-mg daily dose. Because patients with a history of TIA or stroke were the only group in which the risk of bleeding with prasugrel outweighed the benefits, prasugrel is contraindicated in this patient population.

In contrast to the thienopyridines, ticagrelor is a cyclopentyltriazolopyrimidine and is not a prodrug that requires hepatic conversion in order to provide its antiplatelet effect. Ticagrelor is structurally an adaptation of adenosine triphosphate (ATP), which is a known P2Y\textsubscript{12} receptor antagonist. Although the thienopyridines bind irreversibly to the P2Y\textsubscript{12} receptor for the life of the platelet by a disulfide bond, ticagrelor has shown both reversible and non-competitive binding to the P2Y\textsubscript{12} receptor at a site different from that of the endogenous agonist ADP.\textsuperscript{72} Similar to prasugrel, loading and maintenance doses of ticagrelor provide both faster and more potent platelet inhibition than clopidogrel.\textsuperscript{73–75} Data analyses supporting crushed ticagrelor tablet administration show that this may offer advantages in critical care patients.\textsuperscript{76} Pharmacodynamic data analyses show that patients found to be nonresponders to clopidogrel consistently become responders when given ticagrelor.\textsuperscript{75} The reversible binding of ticagrelor requires twice-daily dosing for sustained P2Y\textsubscript{12} receptor inhibition. Twice-daily CV medications have poorer adherence than once-daily medications.\textsuperscript{150} Although ticagrelor produces greater platelet inhibition than clopidogrel, patients who missed a single dose of ticagrelor had platelet inhibition similar to those receiving clopidogrel at 24 hours.\textsuperscript{74} Therefore, patients missing a single dose retain a pharmacodynamic response similar to that with clopidogrel. Despite the reversible binding, platelet function recovery to the level of clopidogrel at 5 days still takes about 3 days with ticagrelor. Even with the faster return of platelet function after discontinuing ticagrelor, a 5-day hold is still recommended before CABG or major surgery. This recommendation is based on the similar
rates of major bleeding in the Platelet Inhibition and Patient Outcomes (PLATO) trial for clopidogrel and ticagrelor when the agents were held for 5 days before CABG surgery.\textsuperscript{1,2,77}

Although ticagrelor does not require hepatic activation to induce its antiplatelet effect, it is metabolized to an active metabolite and many inactive metabolites by CYP3A4 and CYP3A5.\textsuperscript{78} Therefore, CYP3A4 inhibitors have the potential to increase the risk of bleeding, and inducers may reduce its efficacy. Currently, strong CYP3A4 inhibitors and inducers should not be coadministered with ticagrelor.\textsuperscript{42} Moderate CYP3A4 inhibitors such as diltiazem and amiodarone may have a proportional effect on ticagrelor exposure, but they are not contraindicated.\textsuperscript{79} Because some statins have significant CYP3A4 metabolism, coadministration of ticagrelor with more than 40 mg of simvastatin or lovastatin could increase the risk of myopathy and should be avoided. Ticagrelor is also a substrate and inhibitor of P-glycoprotein. Therefore, new steady-state digoxin concentrations should be monitored when initiating ticagrelor therapy.\textsuperscript{80} P-glycoprotein inhibitors such as cyclosporine increase the exposure of ticagrelor, but no dose adjustment is needed.\textsuperscript{42}

In addition to its antiplatelet effects, ticagrelor has been shown in preclinical studies to interfere with adenosine metabolism and increase adenosine concentrations by inhibition of adenosine uptake by erythrocytes. This interaction probably occurs through inhibition of the sodium-independent equilibrative nucleoside transporter 1 (ENT-1).\textsuperscript{81–83} Erythrocyte ENT-1 is responsible for uptake of adenosine into the cell, where it is metabolized by several mechanisms. The ability of ticagrelor to inhibit adenosine’s uptake by ENT-1 is likely because of the similar chemical structure of the two molecules. This interaction produces an increase in adenosine exposure. The quantifiable impact of the increased adenosine exposure is not fully understood, but it may offer clinical advantages and disadvantages to ticagrelor. Studies have shown that ticagrelor can augment both endogenous and exogenous adenosine-induced coronary blood flow in a canine model as well as in healthy volunteers.\textsuperscript{81,82} This increase in coronary blood flow may provide a clinical advantage by producing sustained and elevated
adenosine concentrations in ischemic tissues leading to improved perfusion. Increased adenosine exposure may also explain some of the unique adverse effects shown with ticagrelor (i.e., dyspnea, ventricular pauses, and gout) that are not typically seen with the thienopyridine P2Y<sub>12</sub> inhibitors. It has been shown that continuous infusions of adenosine can produce dyspnea without bronchospasm. Continuous infusions of adenosine have also shown the ability to produce sinoatrial nodal pauses, compared with the more common occurrence of atrioventricular (AV) block produced by bolus doses of adenosine. The increase in gout may be explained by the fact that uric acid is a breakdown product of purine (adenosine) metabolism.

The efficacy and safety of ticagrelor has been shown in patients with NSTE ACS and STEMI in the PLATO trial. The regimen of a ticagrelor loading dose of 180 mg followed by 90 mg twice daily provided a significant reduction in CV death, MI, and stroke (9.8% vs. 11.7%; p<0.001), as well as stent thrombosis (1.3% vs. 1.9%; p=0.009), compared with a 300- or 600-mg loading dose of clopidogrel followed by 75 mg daily. The loading dose of clopidogrel did not affect the study results. Of interest, there was not only a significant reduction in MI, as typically shown in these trials, but also a significant reduction in CV mortality (4.0% vs. 5.1%; p=0.001), which is rarely shown with DAPT. It is unknown whether this reduction in CV mortality is the result of the more potent antiplatelet effect of ticagrelor compared with clopidogrel or the result of improved adenosine-induced coronary perfusion. Using ticagrelor as part of DAPT did increase the risk of major bleeding compared with clopidogrel (4.5% vs. 3.8%; p=0.03) without an increase in life-threatening bleeding, ICH, or fatal bleeding. The incidence of dyspnea, Holter monitor–detected bradycardia, and gout was also significantly higher in patients receiving ticagrelor compared with clopidogrel. Most cases of dyspnea are mild to moderate in severity and resolve in 1–2 weeks. Patients with a history of heart failure, chronic obstructive pulmonary disease, or other causes of dyspnea are not at higher risk of developing ticagrelor-related dyspnea. Although patients at risk of bradycardia (known sick sinus syndrome, second- or third-degree AV conduction block, or previously
documented syncope suspected to be because of bradycardia unless treated with a pacemaker) were not enrolled in the PLATO trial, there was no difference in symptomatic events. The proposed mechanism behind these unique adverse effects is ticagrelor’s competition with adenosine for ENT-1 and its delayed adenosine metabolism. This mechanism is supported by the lack of a sustained impact of these adverse effects. Because of the elevation in adenosine produced as a result of the acute ischemia of an ACS event in local tissues, the adverse effects of dyspnea and ventricular pauses are typically seen early in ticagrelor therapy. When the ischemic stimulus is reduced during the next 30 days, the rates of these adverse effects are reduced, and the need to discontinue therapy is rare.

Ticagrelor is contraindicated in patients receiving a chronic dose of aspirin greater than 100 mg daily. This recommendation is based on results from a subanalysis of the PLATO trial. In this analysis, the benefit of ticagrelor appeared to be attenuated in patients enrolled in North America, specifically the United States. Actually, patients in the United States enrolled in the PLATO trial had a numerical increase in the primary end point with the use of ticagrelor compared with clopidogrel (11.9% vs. 9.5%; p=0.1459), as well as in each of the individual components of the composite end point. This effect may have been a result of the higher maintenance dose of aspirin used in the United States compared with the rest of the world. Patients in the United States were more likely to take a median maintenance aspirin dose of at least 300 mg daily (53.6%) compared with the rest of the world (1.7%). Patients enrolled in the United States who received a maintenance aspirin dose of at least 300 mg daily had an increase in the risk of ischemic events with the use of ticagrelor compared with clopidogrel (hazard ratio [HR] 1.62; 95% confidence interval [CI], 0.99–2.64) but a reduction in ischemic events if a maintenance dose of aspirin was 100 mg daily or less (HR 0.73; 95% CI, 0.40–1.33). The finding that the aspirin dose affected ischemic outcomes in patients receiving ticagrelor was not just a U.S. phenomenon. In patients in the rest of the world, it was also shown that aspirin dose influenced ischemic outcomes, with patients receiving a lower maintenance dose
of aspirin having benefit with ticagrelor compared with clopidogrel (HR 0.78; 95% CI, 0.69–0.87) that seemed to be lost with a higher maintenance dose of aspirin (HR 1.23; 95% CI, 0.71–2.14). Consequently, a maintenance dose of aspirin 75–100 mg daily is recommended in order for ticagrelor to show the benefits of ticagrelor over clopidogrel.88

Cangrelor is currently the only available intravenously administered P2Y<sub>12</sub> inhibitor. As with ticagrelor, cangrelor is structurally derived from ATP and provides reversible inhibition of the P2Y<sub>12</sub> receptor by binding in a different location for ADP. Even with loading doses, oral P2Y<sub>12</sub> inhibitors take a minimum of 1–2 hours to obtain maximum platelet inhibition and 4–7 days for platelet recovery after discontinuation. Cangrelor achieves maximum platelet inhibition within about 2 minutes of an intravenous bolus dose, with restoration of normal platelet reactivity within 1–2 hours of cessation of the infusion.89,90 Cangrelor has an elimination half-life of less than 9 minutes and is eliminated by ATPases in the blood. Therefore, hepatic or renal dysfunction is unlikely to affect the pharmacokinetics of cangrelor. The fast return to normal platelet function may provide safety advantages for cangrelor over other P2Y<sub>12</sub> inhibitors in the context of bleeding or transition to CABG surgery.91

The CHAMPION PHOENIX trial evaluated a strategy of pre-PCI cangrelor (30-mcg/kg bolus dose, followed by a 4-mcg/kg per minute continuous infusion) and post-PCI clopidogrel compared with only post-PCI clopidogrel (300-or 600-mg loading dose, followed by 75 mg daily).92 Patients with ACS constituted 44% of the total patients undergoing PCI in the trial (26% NSTEMI and 18% STEMI). At 48 hours, cangrelor provided a significant reduction in death, MI, ischemia-driven revascularization, and stent thrombosis compared with clopidogrel (4.7% vs. 5.9%; p=0.005), without an increase in major bleeding (minor bleeding was higher with cangrelor). Because the chemical structure of cangrelor is similar to that of ticagrelor, dyspnea was reported more with the use of cangrelor, but the shorter drug exposure time likely contributed to a lower incidence (1.2%) and discontinuation rate (0.1%) with cangrelor than with ticagrelor in the
PLATO trial (13.8% and 0.9%, respectively). The utility of cangrelor in patients preloaded with clopidogrel is unknown, as is how it might compare with faster-acting prasugrel and ticagrelor.

Cangrelor may interfere with the binding of the active metabolites of clopidogrel and prasugrel. Studies have shown that when clopidogrel is given with cangrelor, the ability of the thienopyridines to irreversibly inhibit platelet function is reduced. It is thought that the reversible inhibitor cangrelor directly prevents the binding of the short-lived, but irreversible active metabolites. Once the infusion is discontinued, no impact on the pharmacodynamic effect of clopidogrel was seen. This same interaction would be expected with prasugrel. Therefore, it is important that if cangrelor is used, the loading dose of the thienopyridine not be given until the cangrelor infusion has been discontinued.

Glycoprotein IIb/IIIa Inhibitors
Because binding of fibrinogen to the platelet glycoprotein (GP) IIb/IIIa receptor represents the final common step in platelet aggregation, inhibition of this interaction represents an ideal target for pharmacotherapy. Three GP IIb/IIIa inhibitors are currently available for use, with all agents available intravenously only. Abciximab is a chimeric human-murine monoclonal antibody Fab fragment that blocks GP IIb/IIIa receptor-fibrinogen binding. Abciximab has irreversible binding to the GP IIb/IIIa receptor, with platelet function recovery occurring over about 48 hours after discontinuation of the infusion. Unbound abciximab is eliminated rapidly, with less than 5% being detectable in plasma 2 hours after a bolus. Because of the strong binding of abciximab to the GP IIb/IIIa receptor, the drug/receptor ratio is about 2:1. Therefore, platelet transfusions can absorb the excess abciximab and would be effective in the management of a major bleeding episode.

Eptifibatide and tirofiban are commonly called “small-molecule” GP IIb/IIIa inhibitors because they are peptide and nonpeptide inhibitors of the GP IIb/IIIa receptor, respectively, and have a much small molecular weight than abciximab. These agents have reversible binding of the GP
IIb/IIIa receptor. Therefore, platelet function recovery occurs in 2–4 hours after discontinuation of the infusion.\textsuperscript{95} The reversible binding of the small-molecule agents requires that they overwhelm the ability of fibrinogen to bind to the GP IIb/IIIa receptor with high concentrations and a drug/receptor ratio that is around 500–1,000:1. Consequently, platelet transfusion would be unable to absorb excess drug and would not be helpful in the management of bleeding with eptifibatide or tirofiban.\textsuperscript{2,95}

In addition to bleeding, GP IIb/IIIa inhibitors can cause thrombocytopenia in about 1\% of patients receiving abciximab and 0.5\% of patients receiving eptifibatide and tirofiban. Because GP IIb/IIIa inhibitors should be administered with a heparin, it is important to differentiate GP IIb/IIIa inhibitor–induced thrombocytopenia from heparin-induced thrombocytopenia (HIT). Thrombocytopenia from a GP IIb/IIIa inhibitor occurs more rapidly (within hours), and the platelet count nadir is typically lower (about 20,000) than in HIT. Unlike patients with HIT, if thrombocytopenia occurs with abciximab, platelet transfusion can be administered. Although the efficacy of platelet transfusion for thrombocytopenia from eptifibatide or tirofiban may be limited, it would unlikely be harmful in HIT.

Glycoprotein IIb/IIIa inhibitors have been extensively studied in patients with ACS.\textsuperscript{96–101} Many of the initial studies were conducted before the standard use of DAPT. In the Intracoronary Stenting and Antithrombotic Regimen: Rapid Early Action for Coronary Treatment (ISAR-REACT 2) trial, patients receiving a 600-mg loading dose of clopidogrel and undergoing PCI for NSTE ACS had a significant reduction in CV events with a GP IIb/IIIa inhibitor (abciximab) compared with placebo.\textsuperscript{102} Of interest, the benefit was only shown in patients who had a positive troponin (13.1\% vs. 18.3\%; \(p=0.02\)), with no difference in patients without elevated troponins (4.6\% in both groups). Therefore, GP IIb/IIIa inhibitors provide added benefit in the setting of early DAPT, but they should be reserved for high-risk patients with a positive troponin.\textsuperscript{2}

Only one clinical outcome trial has compared the GP IIb/IIIa inhibitors. In the TARGET (Treatment Approaches in Renal Cancer
Global Evaluation Trial) study, patients undergoing PCI had significantly more CV events at 30 days with tirofiban than with abciximab (7.6% vs. 6.0%; p=0.38). All the benefits of abciximab over tirofiban were realized in the 63% of patients with NSTE ACS in the trial (9.3% vs. 6.3%; p<0.05). These results led to the investigation and use of a higher-dose tirofiban regimen. Although subsequent trials have shown no differences between high-dose tirofiban and abciximab, all trials to date have evaluated surrogate end points (ST-segment resolution, myocardial perfusion), and no comparative clinical outcome trials have been conducted.  

Anticoagulant Therapy

Although many antiplatelet agents are given to patients with ACS, a single anticoagulant agent is usually selected. To date, anticoagulant therapy has been targeted either against factor IIa (thrombin) directly or its production by inhibiting factor Xa. Unfractionated heparin (UFH) has been used in the treatment of patients with ACS for several decades. Unfractionated heparin provides its anticoagulant effect by first binding to antithrombin (AT) and increasing its potency by 1,000-fold. The UFH-AT complex inhibits several clotting factors, with most of the impact coming from inhibition of factor Xa and thrombin. Because of the size of the UFH molecule, it inhibits these two factors in an equal ratio.

According to experience, UFH can be used across the spectrum of ACS and regardless of the management strategy. The recommended dosing of UFH has changed several times during its history in an attempt to maximize efficacy and minimize bleeding. Currently, the recommended dose of UFH is a bolus of 60 units/kg (maximum total dose of 4,000 units) and an initial infusion rate of 12 units/kg/hour (maximum 4,000 units/hour). Because of the unpredictable interpatient variability of the anticoagulant response of UFH, therapy needs to be monitored with an activated partial thromboplastin time (aPTT). The aPTT should be measured every 6 hours until two consecutive readings are within the therapeutic range, as determined by the individual institution’s protocol, and then every 24 hours for the duration of UFH.
therapy. If a dose adjustment is made, the same monitoring schedule should be reinitiated. Platelet counts should also be monitored daily or every other day for HIT. Although HIT typically presents 5 days or more after UFH exposure, it can occur within hours if the patient has been exposed to heparin in the past 3 months. If HIT is suspected, UFH should be discontinued, and anticoagulation with an intravenous direct thrombin inhibitor should be provided.

Compared with UFH, low-molecular-weight heparins (LMWHs) provide a predictable anticoagulant dose response, no need for routine therapeutic monitoring, and a lower incidence of HIT. As with UFH, LMWH must also bind to AT to provide its anticoagulant activity, with more impact against factor Xa than thrombin (3–4:1 ratio). Even though the risk of HIT is lower with LMWH than with UFH, the monitoring of platelet counts is still warranted. Because of the 90% cross-reactivity between HIT antibodies from LMWH and UFH, LMWH is not considered a safe alternative in patients who develop HIT from UFH. Although other LMWHs are available, enoxaparin is the most widely studied agent and is the only LMWH discussed in the ACC/AHA guidelines.1,2 The dosing of enoxaparin varies depending on the diagnosis and management strategy selected. Therefore, careful attention needs to be maintained to prevent inappropriate dosing and to maximize efficacy and safety. Although most patients receiving an LMWH do not require therapeutic monitoring, an anti-factor Xa (anti-Xa) level may be desired in certain patient populations. Groups in which anti-Xa monitoring may be helpful are pediatric patients, pregnant patients, patients with obesity (greater than 190 kg), and patients with severe renal insufficiency. The target peak anti-Xa level would be 0.3–0.7 IU/mL, obtained 4 hours after the third dose. Although pediatric and pregnant patients rarely have ACS, it is more common in patients with obesity and severe renal insufficiency. Because patients with ACS typically receive anticoagulant therapy for a few days, the utility of anti-Xa monitoring in these patients may be limited.

Fondaparinux is currently the only pentasaccharide available for use. Fondaparinux must also bind to AT, with its anticoagulant activity
specifically targeted against factor Xa, with no activity against thrombin. Fondaparinux also provides a predictable anticoagulant dose response and no need for therapeutic monitoring. Although there are case reports of thrombocytopenia with fondaparinux, the incidence is thought to be extremely rare. Given the lack of antibody cross-reactivity, it is reasonable to consider fondaparinux in patients with a history of HIT. Given the long half-life of fondaparinux, the dose in patients with ACS is 2.5 mg subcutaneously once daily. Fondaparinux is contraindicated in patients with a creatinine clearance of less than 30 mL/minute/1.73 m$^2$ because of the significant degree of renal elimination. There can also be accumulation in patients with a creatinine clearance of 30–60 mL/minute/1.73 m$^2$, but this is typically not a factor with the short duration of therapy in patients with ACS.

As with LMWH, most patients do not require therapeutic monitoring, although it may be desired in certain special populations. A chromogenic assay of anti-Xa calibrated with fondaparinux produces reliable and reproducible results. Fondaparinux needs to be used to form the standard curves to measure fondaparinux concentrations. Results obtained using an LMWH standard curve are less accurate, and standard curves using UFH are completely inaccurate and should not be used. Peak plasma concentrations are typically achieved within 3 hours after dosing.

Bivalirudin is an intravenously administered direct thrombin inhibitor. Therefore, bivalirudin does not have to first bind to AT to provide its anticoagulant effect. By not having to bind to AT, bivalirudin can inhibit not only free or soluble thrombin, similar to UFH and LMWH, but also fibrin-bound thrombin. Fibrin-bound thrombin is still enzymatically active, but the bulky AT-anticoagulant complexes are unable to gain access. The clinical benefit of bivalirudin’s inhibition of this larger pool of thrombin is difficult to quantify. Bivalirudin is only used in patients with ACS who receive PCI and can be monitored with an activated clotting time (ACT) in the catheterization laboratory. Bivalirudin initiated before the patient arrives in the cardiac catheterization laboratory is sometimes monitored with an aPTT, but appropriate goals and subsequent dose adjustments based on aPTT results are not well
established.

**ANTITHROMBOTIC THERAPY IN NSTE ACS**

Treatment of patients with NSTEMI consists of two initial strategies (Figure 33.1). One approach is the early invasive strategy, where the intent is to take the patient to the cardiac catheterization laboratory for angiography and perform PCI (usually with stenting), if necessary. The other approach is termed an ischemia-driven strategy, which has also been called the non-invasive strategy, medical management, or a conservative approach. In this strategy, the intent is to treat the patient medically without PCI. If the patient has no relief or has a recurrence of ischemia, the patient is evaluated with angiography, and PCI is performed if the patient is a candidate.

Regardless of the management strategy selected, all patients should receive an initial dose of chewable aspirin 162–325 mg as soon as possible, followed by 81 mg daily.\(^1\)\(^2\) A clopidogrel loading dose, followed by maintenance doses, could be substituted in patients with a hypersensitivity or GI intolerance to aspirin. Aspirin desensitization may be considered in cases of hypersensitivity after the patient has stabilized. Dual antiplatelet therapy with a P2Y\(_{12}\) inhibitor should be administered to all patients without a contraindication. If DAPT is administered before the management approach has been decided, a 300- or 600-mg loading dose of clopidogrel or a 180-mg loading dose of ticagrelor should be given.\(^1\)\(^2\) These agents are preferred because they have shown efficacy in both an ischemia-driven and an early invasive management strategy.\(^{39,77,114}\)

**Early Invasive Strategy**

Compared with primary PCI in the setting of STEMI, the need for immediate reperfusion in the setting of NSTEMI has not been proved to improve clinical outcomes. The optimal timing of coronary angiography has not been determined. Although some institutions may prefer an early (within 24 hours) or a delayed (25–72 hours) approach, most studies evaluating an early invasive strategy for NSTEMI have
deferred angiography and potential revascularization for 12–72 hours.\textsuperscript{2} This provides time to optimize and maximize pharmacotherapy.

An initial chewable aspirin dose should have been given even before the management strategy has been determined. If the patient for some reason has not received aspirin, the patients not on chronic aspirin should receive a dose of 325 mg as soon as possible before PCI, and those on chronic aspirin should receive a dose of 81–325 mg (class I, LOE B).\textsuperscript{2} Doses of aspirin after PCI should be 81 mg daily (class IIa, LOE B).\textsuperscript{2}

Patients undergoing PCI should be given a loading dose of a P2Y\textsubscript{12} inhibitor before the procedure (class 1, LOE A recommendation).\textsuperscript{2} If clopidogrel is selected, the loading dose should be 600 mg instead of 300 mg. This is based on data analyses showing that a 600-mg loading dose provides more potent platelet inhibition as well as faster platelet inhibition. Pharmacodynamic studies have shown that the 300-mg loading dose provides maximal platelet inhibition in 6–8 hours.\textsuperscript{115} Despite these pharmacodynamic data with a 300-mg loading dose, data evaluations from the CREDO (Clopidogrel for the Reduction of Events During Observation) trial suggest that there is no benefit in clinical outcomes unless the 300-mg loading dose is given 15 hours before PCI.\textsuperscript{116} A 600-mg loading dose can achieve maximum platelet inhibition within 2–4 hours.\textsuperscript{117} Using a 600-mg loading dose has also shown a significant reduction in CV events compared with a 300-mg loading dose in patients with ACS undergoing PCI.\textsuperscript{118} Although a 900-mg loading dose has also been evaluated, there was no increase in platelet inhibition compared with a 600-mg dose.\textsuperscript{119} It appears that there is a saturation of conversion to active compound, and no improved efficacy would be expected. Given the superior efficacy shown in the TRITON-TIMI 38 and PLATO trials, prasugrel and ticagrelor, respectively, are recommended to be used over clopidogrel (class IIa, LOE B).\textsuperscript{2,68,77}
Figure 33.1 Treatment algorithm for management of non–ST-segment elevation acute coronary syndrome.

a If the last dose of enoxaparin is given within 8 hours of PCI, no additional anticoagulant is needed. If the last dose of enoxaparin is given 8–12 hours before PCI, an additional IV bolus dose of 0.3 mg/kg of enoxaparin should be given at the time of PCI.

b Bivalirudin should not be used in this setting if a glycoprotein IIb/IIIa inhibitor is being used because the patient has high-risk features (e.g., positive troponin).

c Data for high-dose tirofiban in this setting are based on surrogate end point data.

d Use of upstream or early glycoprotein IIb/IIIa inhibitor therapy may be preferred only in patients who have not, or will not, receive a loading dose of an oral P2Y₁₂ inhibitor or
The role of GP IIb/IIIa inhibitors has become more complex in the past decade. Currently, use of these agents should be reserved for patients with high-risk features such as an elevated troponin. Once the decision to use a GP IIb/IIIa inhibitor is made, the timing of initiating the agent also needs to be considered. One approach is to provide an upstream GP IIb/IIIa inhibitor, which is initiating the agent early, several hours or even days before PCI. The other approach is waiting to administer the GP IIb/IIIa inhibitor at the time of PCI. These approaches have been compared in the EARLY-ACS (Early Glycoprotein IIb/IIIa Inhibition in Non-ST-segment Elevation Acute Coronary Syndrome) trial. In this trial, upstream GP IIb/IIIa inhibitor use did not improve clinical outcomes but did produce more major bleeding. Therefore, there seems to be limited justification for this approach. One instance when the upstream approach may be rational is when patients with high-risk features are not planned to receive P2Y$_{12}$ therapy until the time of PCI. The delayed use of P2Y$_{12}$ inhibitors is occasionally employed by clinicians or institutions that prefer to know when the coronary anatomy is amendable to PCI and when CABG surgery has been ruled out. The justification follows that this avoids the need to wait 5–7 days for platelet recovery from P2Y$_{12}$ inhibitor therapy.

Anticoagulant therapy with UFH in patients with NSTE ACS using an invasive approach is a class I, LOE C recommendation. Enoxaparin was compared with UFH in patients with NSTE ACS with an invasive approach in the SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial. The overall results of the trial showed no difference between the agents in the incidence of death or MI and showed an increase in major bleeding in patients receiving enoxaparin. Of interest, 39% of
patients in the trial received both agents sometime during the study. It obviously becomes difficult to determine how two agents are different if patients receive both agents. When patients who received only UFH or enoxaparin throughout the study are analyzed, there is a significant reduction in death and MI with the use of enoxaparin compared with UFH, without an increase in major bleeding. Patients who have received their last subcutaneous dose 8–12 hours before PCI, or have received less than two subcutaneous doses of enoxaparin, should receive an additional 0.3-mg/kg intravenous bolus dose at the time of PCI to ensure adequate anticoagulant effect (class I, LOE B).2,121

Although fondaparinux is discussed in the ACC/AHA NSTE ACS guidelines, use in the United States with PCI is limited. In the Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS)-5 trial, patients undergoing PCI receiving fondaparinux have significantly higher rates of catheter thrombosis than do patients receiving enoxaparin.122,123 Therefore, using fondaparinux alone in patients undergoing PCI is a class III, LOE B recommendation.2 If patients are receiving fondaparinux and need to receive PCI, additional anticoagulant therapy with UFH is required. The dose of UFH at the time of PCI differs depending on whether the patient is taking a GP IIb/IIIa inhibitor (85 units/kg) or not (60 units/kg). Additional doses of UFH may need to be given during the procedure based on the ACT. Therefore, in patients for whom it is expected that PCI will be needed, fondaparinux is typically avoided.

Bivalirudin is also an alternative for anticoagulant therapy in patients with NSTE ACS with an early invasive approach (class I, LOE B).2 Evidence for using bivalirudin in these patients comes from the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial.124 Compared with many other ACS trials of AT, the ACUITY trial used a quadruple composite end point (death, MI, unplanned revascularization for ischemia, and major bleeding) and a fairly liberal definition for major bleeding. Consequently, a 5-cm bruise was counted as equal to a death or MI as an end point event. Regardless, patients receiving a heparin (UFH or LMWH) and a GP IIb/IIIa inhibitor had efficacy and safety similar to patients receiving bivalirudin and a GP
Ilb/IIia inhibitor. Therefore, the ACUITY trial showed that bivalirudin and a GP Ilb/IIia inhibitor therapy should not be used together because of a lack of any benefit, and this approach would significantly increase costs compared with a heparin and a GP Ilb/IIia inhibitor. The group receiving bivalirudin alone with only a “bailout” GP Ilb/IIia inhibitor had a reduction in the primary end point compared with a heparin and a GP Ilb/IIia inhibitor, which was driven by a reduction in major bleeding (3.0% vs. 5.7%; p<0.001). Although rescue or bailout GP Ilb/IIia is commonly used, this has never been prospectively evaluated.

The ability to use bivalirudin on its own without a GP Ilb/IIia inhibitor can significantly reduce the cost of antithrombotic therapy and has led to increased bivalirudin use in patients with NSTE ACS and an early invasive approach. However, using bivalirudin in this setting is not without controversy. The ischemic end points in the trial trended higher with bivalirudin alone than with a heparin and a GP Ilb/IIia inhibitor by 0.5%, which grew to 1% when higher-risk troponin-positive patients were evaluated.\textsuperscript{124,125} Given the known benefit of GP Ilb/IIia inhibitor in patients who are troponin positive from the ISAR-REACT 2 trial, questions remain whether bivalirudin alone should be used in all patients. Although the ISAR-REACT 4 trial tried to compare bivalirudin alone with a heparin and a GP Ilb/IIia inhibitor in these higher-risk patients, the trial overestimated the suggested difference (4.6% vs. 1% seen in ACUITY) and was underpowered.\textsuperscript{126} Even in the ISAR-REACT 4 trial, patients with higher troponin concentrations (greater than 0.12 mcg/L) show a 2.3% benefit in patients receiving the GP Ilb/IIia inhibitor. This was a subgroup analysis of the overall data and was not powered to show significance. More recent analyses have also suggested that bivalirudin alone does not provide significant benefit over UFH alone.\textsuperscript{127–129} Despite these questions, the availability of generic bivalirudin makes the cost of bivalirudin alone even more attractive.

**Ischemia-Driven Strategy**
As previously mentioned, chewable aspirin should have been administered at a dose of 162–325 mg as soon as possible on
presentation, followed by 81 mg daily. Although some clinicians may believe that DAPT is given only in patients receiving PCI and stents for prevention of stent thrombosis, DAPT is also indicated in patients who do not undergo PCI. The role of DAPT became evident after the results of the CURE trial.\textsuperscript{39} The support for this regimen of clopidogrel with aspirin in patients not receiving PCI comes from the fact that about 80% of the patients in the CURE trial were treated with an ischemia-driven approach. The 300-mg loading dose of clopidogrel is supported by the results of the CURRENT–OASIS 7 trial.\textsuperscript{118} In this trial, a higher loading dose of clopidogrel 600 mg provided no additional benefit over a 300-mg loading dose in the patients with NSTE ACS undergoing an ischemia-driven approach. In the PLATO trial, the benefit of ticagrelor over clopidogrel as part of DAPT was consistent regardless of whether the patient was treated with PCI (HR 0.84) or with an ischemia-driven approach (HR 0.85).\textsuperscript{77} Prasugrel was compared with clopidogrel in patients with NSTE ACS using an ischemia-driven approach in the TRILOGY-ACS (Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes) trial, with no difference in efficacy or safety between the agents.\textsuperscript{130} The ACC/AHA guidelines provide a class I, LOE B recommendation for using clopidogrel (300-mg loading dose followed by 75 mg daily) or ticagrelor (180-mg loading dose followed by 90 mg twice daily) as part of DAPT with an ischemia-driven approach.\textsuperscript{2} Up to 1 year of DAPT is recommended in patients with an ischemia-driven approach for NSTE ACS. A class IIa, LOE B recommendation is given for the use of ticagrelor over clopidogrel according to the results of the PLATO trial.\textsuperscript{2,77} Although prasugrel provides no efficacy or safety differences compared with clopidogrel, the higher cost of prasugrel makes its selection unreasonable.

Triple antiplatelet therapy with a GP IIb/IIIa inhibitor has no role in patients with an ischemia-driven approach. Abciximab provided no benefit over placebo with an ischemia-driven approach in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) IV trial.\textsuperscript{131} There was also no benefit of eptifibatide or tirofiban in the subgroup of patients with an
ischemia-driven approach from the PURSUIT and PRISM-PLUS (Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms) trials, respectively.\textsuperscript{97,98}

Anticoagulant therapy is also provided for the duration of hospitalization. Using UFH is reasonable and has a class 1, LOE B recommendation for use for 48 hours.\textsuperscript{2} Enoxaparin has shown a significant reduction in CV events without an increase in major bleeding compared with UFH with an ischemia-driven approach in the ESSENCE (Efficacy and Safety of Subcutaneous Enoxaparin in Non–Q wave Coronary Events) and TIMI – 11b trials.\textsuperscript{132,133} The use of enoxaparin is given a class 1, LOE A recommendation in the ACC/AHA guidelines because of these results.\textsuperscript{2} In patients with an ischemia-driven approach, enoxaparin is dosed 1 mg/kg subcutaneously every 12 hours. Patients with severe renal insufficiency should receive the same dose given every 24 hours. Although an initial 30-mg intravenous loading dose can be given, it is uncertain whether this provides any clinical benefit.\textsuperscript{2,133}

Fondaparinux had similar efficacy and less major bleeding than enoxaparin with an ischemia-driven approach in the OASIS-5 trial.\textsuperscript{122} Although this mainly European-based trial had some external validity issues that may explain the difference in bleeding, it seems reasonable to prefer fondaparinux in patients considered to have a higher risk of bleeding (class 1, LOE B).\textsuperscript{2} Bivalirudin has not been evaluated outside the setting of PCI and therefore would not be considered an option with an ischemia-driven approach.

**ANTITHROMBOTIC THERAPY**

Because of the extensive thrombus with almost 100% occlusion of the infarct-related coronary artery, patients with STEMI need immediate reperfusion therapy. Reperfusion should typically occur within 12 hours of symptom onset, but the sooner the better. Irreversible myocardial cell death occurs within 1–2 hours of symptom onset with completion of the area of infarct within 6–12 hours. Patients with ongoing ischemia...
and a large area of myocardium at risk or patients with hemodynamic instability may benefit from reperfusion therapy between 12 and 24 hours. Regardless of the reperfusion therapy selected, antithrombotic therapy is critical to optimize outcomes (Figure 33.2). Although selection and dosing of appropriate antithrombotic agents may be similar to management of NSTE ACS, there are important differences to consider (Table 33.7).

**Primary PCI**

Patients who can receive timely reperfusion with a door-to-balloon time of 120 minutes or less should receive primary PCI.\(^1\) In this setting, primary PCI has shown better vessel patency and has less risk of reocclusion and ICH that comes with the use of fibrinolytic therapy.

Management of oral antiplatelet therapy in patients with STEMI with primary PCI is the same as in those with NSTE ACS with an early invasive approach. An initial loading dose of chewable aspirin is indicated (class I, LOE B), with a maintained dose of 81 mg daily being preferred (class IIa, LOE B).\(^1\) If clopidogrel is the P2Y\(_{12}\) inhibitor being used, a 600-mg loading dose should be used to provide more rapid platelet inhibition. A 60-mg loading dose of prasugrel or a 180-mg loading dose of ticagrelor can also be used because these agents both showed significant benefit over clopidogrel in the patients with STEMI in the TRITION-TIMI 38 and PLATO trials, respectively.\(^70,77\) All P2Y\(_{12}\) inhibitors, even prasugrel, should be administered as soon as possible before the patient arrives in the cardiac catheterization laboratory. Because of the high-risk nature of patients with STEMI, GP IIb/IIIa inhibitors have shown a reduction in ischemic events in patients undergoing primary PCI. Although most of the clinical evidence exists with abciximab (class IIa, LOE A), eptifibatide and high-dose tirofiban are also listed as options because of surrogate end point data (class IIa, LOE B) and the fact that most of the abciximab data were generated before aggressive use of P2Y\(_{12}\) inhibitor loading doses.\(^1\)

Intracoronary abciximab (0.25-mg/kg bolus only) has also shown benefit and may be considered (class IIb, LOE B).\(^1,134-136\) Because
about 90% of a total dose of abciximab is given in the bolus anyway, this approach may be all that is needed while P2Y\textsubscript{12} inhibitor therapy takes effect. This approach requires more study before it should completely replace standard dosing of abciximab. This should not be tried with boluses of small-molecule GP IIb/IIIa inhibitors because most of their total doses are provided during the infusions.
**Figure 33.2** Treatment algorithm for management of ST-segment elevation myocardial infarction.

a A clopidogrel loading dose has not been evaluated in patients > 75 years receiving fibrinolysis; therefore, the risk of bleeding in these patients is unknown.

b The first subcutaneous dose of enoxaparin should follow within 15 min of the intravenous
There are decades of experience with the use of UFH as anticoagulant therapy in patients undergoing primary PCI for STEMI (class I, LOE C).\(^1\) Because of how rapid PCI needs to occur in the treatment of STEMI and because anticoagulant therapy is not typically needed post-procedure, bolus doses are all that may be required. If a GP IIb/IIIa inhibitor is also being given, a bolus dose of 50–70 units/kg intravenously is recommended to achieve a therapeutic ACT of 200–250 seconds. If a GP IIb/IIIa inhibitor is not being used, a higher dose of 70–100 units/kg intravenously is recommended to achieve a therapeutic ACT of 250–300 seconds with the HemoTec device or 300–350 seconds with the Hemochron device.

Bivalirudin use in primary PCI is supported by the HORIZONS (Harmonizing Outcomes with Revascularization and Stents) trial.\(^{137}\) Using bivalirudin alone had similar efficacy with significantly less major bleeding than did using a heparin and a GP IIb/IIIa inhibitor (4.9% vs. 8.3%; \(p<0.001\)). Patients receiving bivalirudin alone had a significant increase in the rate of acute stent thrombosis (1.3% vs. 0.3%). As with the ACUITY trial, this probably represents the lack of adequate antiplatelet therapy with the rapid use of PCI in STEMI and the inability of clopidogrel and bivalirudin to provide protection in this acute time interval.\(^{124}\) As in the ACUITY trial, GP IIb/IIIa inhibitors were reserved for bailout therapy only. As previously discussed, the lack of benefit of bivalirudin alone compared with UFH alone has raised questions about the role of bivalirudin.\(^{128,129}\) Of note, a definitive study has yet to be completed to answer this question. Using bivalirudin in primary PCI for STEMI is a class I, LOE B recommendation.\(^1\)
Although a 2.5-mg intravenous dose followed by subcutaneous dosing of fondaparinux was evaluated in the OASIS-6 trial, fondaparinux is not commonly used in primary PCI.\textsuperscript{138} There was no difference in the rates of death or MI with the use of fondaparinux compared with UFH in 31% of patients undergoing primary PCI in the OASIS-6 trial. As in the OASIS-5 trial, there was an increase in catheter thrombosis in patients receiving fondaparinux.\textsuperscript{123,138} Therefore, if fondaparinux is used in primary PCI, UFH must be given at the time of PCI as with NSTE ACS and an early invasive management. Because of how rapidly PCI should occur in STEMI, there seems to be little utility to fondaparinux in this setting. Although enoxaparin is not given a recommendation for or against use in the ACC/AHA guidelines, the ATOLL (STEMI Treated with Primary Angioplasty and Intravenous Lovenox or Unfractionate Heparin) trial suggests outcomes similar to those with UFH, and a meta-analysis supports a reduction in mortality compared with UFH with a one-time intravenous dose of enoxaparin 0.5 mg at the time of PCI.\textsuperscript{139,140}
Reperfusion with Fibrinolysis

Fibrinolytic Therapy
Fibrinolytic agents represent the only available pharmacotherapy able to break down a thrombus and open occluded vessels. This is achieved by the agents acting as a tissue plasminogen activator that increases the conversion of plasminogen to the proteolytic enzyme plasmin. Plasmin is then able to cleave fibrin and fibrinogen, hopefully opening the infarct-related artery. Fibrin specificity is a pharmacologic property that may provide benefits. Currently used agents rank in fibrin specificity as tenecteplase > alteplase > reteplase. Agents that are more fibrin-specific may have an efficacy and safety advantage. A more fibrin-specific agent would be expected to have better efficacy because the occluding thrombus is mainly composed of fibrin, and activity on free fibrinogen would not provide benefit. This may be especially true in an “older” thrombus that is more than 2 hours old in which more fibrin would be incorporated in the thrombus. There may also be less bleeding with a fibrin-specific agent because fewer fibrin degradation products, which have antithrombotic activity, are formed by not breaking down both fibrin and fibrinogen. This may also allow more free fibrinogen available for use for potential bleeding episodes. It remains to be determined whether the fibrin specificity of a fibrinolytic agent affects clinical outcomes. The significantly less major bleeding (not ICH), need for transfusion, and reduced mortality in patients presenting within 4–6 hours after symptom onset with the use of tenecteplase compared with alteplase suggest the potential for fibrin specificity to affect outcomes, but this is not definitive. Although alteplase had been the fibrinolytic of choice for more than a decade, the newer bolus-only agents provide easier use and less potential for dosing errors.

Despite the worldwide experience with fibrinolytic therapy, there are limitations that must be considered. Regardless of the fibrinolytic agent used, patency (TIMI grade 2 and 3 flow) is restored in 60%–85% of patients, but only 50%–60% of patients achieve full myocardial reperfusion (TIMI grade 3 flow). Even if optimal myocardial blood
flow is achieved, fibrinolytic therapy has a reocclusion rate of 10%–15%. Fibrinolytic therapy is associated with a higher rate of ICH than is antithrombotic therapy or primary PCI (see Box 33.1). The incidence of ICH has been estimated to occur in 1 in 150–200 treated patients; however, the incidence was slightly higher in the GUSTO-III trial, occurring in about 1 in 100 treated patients.\textsuperscript{142,145,146} Patients with ICH on fibrinolytic therapy is typically a catastrophic event, resulting in death or disabling stroke.

**Adjunctive Antithrombotic Therapy**

As with all other management strategies for ACS, patients receiving fibrinolysis for STEMI should also receive a loading dose of chewable aspirin (class I, LOE A), followed by 81 mg daily (class IIa, LOE B).\textsuperscript{1} Using DAPT with fibrinolysis is more limited than with other areas of ACS management. Clopidogrel is the only P2Y\textsubscript{12} inhibitor to be studied with the use of fibrinolitics; therefore, prasugrel and ticagrelor should not be used.\textsuperscript{46,47} In the CLARITY-TIMI 28 trial, DAPT with clopidogrel and aspirin provided significant benefit over aspirin alone in patients with STEMI receiving fibrinolysis as primary reperfusion therapy (15% vs. 21.7%; \textit{p}<0.001), without an increase in major bleeding or ICH.\textsuperscript{47} Of note, a 300-mg loading dose of clopidogrel was used in this trial, and a 600-mg loading dose has not been investigated and should not be used. Because of concerns about ICH, patients older than 75 years were not evaluated in the CLARITY-TIMI 28 trial. Therefore, patients older than 75 should not receive a loading dose of clopidogrel and should be initiated on 75 mg daily.

---

**Box 33.1. Absolute and Relative Contraindications for Fibrinolytic Therapy in STEMI**

---

**Absolute contraindications**

- Prior intracranial hemorrhage at any time
Prior ischemic stroke within 3 months
- Known malignant intracranial neoplasm (primary or metastatic)
- Known structural cerebral vascular lesion (arteriovenous malformation)
- Suspected aortic dissection
- Active bleeding (excluding menses) or bleeding diathesis
- Significant closed-head or facial trauma within 3 months
- Intracranial or intraspinal surgery within 2 months
- Severe uncontrolled hypertension unresponsive to emergency therapy

Relative contraindications
- History of chronic, severe, poorly controlled hypertension
- Significant hypertension on presentation (systolic blood pressure > 180 mm Hg or diastolic blood pressure > 110 mm Hg)
- Prior ischemic stroke more than 3 months ago
- Dementia
- Traumatic or prolonged cardiopulmonary resuscitation (more than 10 minutes)
- Major surgery within 3 weeks
- Internal bleeding within 2–4 weeks
- Noncompressible vascular punctures
- Pregnancy
- Active peptic ulcer disease
- Oral anticoagulant therapy
- Known intracranial pathology not mentioned in absolute contraindications
Using half-dose fibrinolytic therapy with a GP IIb/IIIa inhibitor has been studied extensively.\textsuperscript{147} Although initial studies showed significant improvement in patency of the infarct-related artery and myocardial perfusion with this combination, no improvement in mortality was shown.\textsuperscript{148} Although the combination did produce a reduction in MI, this did not lead to a reduction in mortality at 1 year and came at the cost of significantly higher major bleeding. Therefore, this combination is no longer recommended.

Many of the initial trials evaluating the efficacy and safety of fibrinolytic therapy used UFH as the anticoagulant. Because of this experience, UFH has a class I, LOE C recommendation from the ACC/AHA for use for 48 hours, or until revascularization, if needed.\textsuperscript{1} Enoxaparin is also recommended for use in patients with STEMI receiving fibrinolysis (class I, LOE A).\textsuperscript{1} In the ExTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment, Thrombolysis in Myocardial Infarction-Study 25) trial, enoxaparin provided a significant reduction in death and MI compared with UFH (9.9% vs. 12.0%; p<0.001).\textsuperscript{149} Although there was an increase in major bleeding with the use of enoxaparin compared with UFH (2.1% vs. 1.4%; p<0.001), there was no difference in ICH. Dosing of enoxaparin in this setting typically requires a 30-mg intravenous loading dose, with subcutaneous dosing to begin within 15 minutes after the intravenous dose is given. Careful attention is needed when dosing enoxaparin in this setting because initial subcutaneous doses are capped, and dosing is different for patients 75 years or older and those with severe renal insufficiency. Enoxaparin therapy should be given for the duration of hospitalization, or up to 8 days or the need for revascularization.

According to the results of the OASIS-6 trial, fondaparinux is given initially as a 2.5-mg intravenous dose followed by 2.5 mg subcutaneously the following day (class I, LOE B).\textsuperscript{1,138} In the OASIS-6 trial, fondaparinux had efficacy (HR 0.96) and safety (HR 0.95) similar to UFH in patients with STEMI receiving fibrinolytic therapy. Similar to
enoxaparin, fondaparinux should be given for the duration of hospitalization, or up to 8 days or the need for revascularization. Anticoagulant therapy with bivalirudin has not been adequately investigated and is not recommended with the use of fibrinolytic therapy.

Follow-up angiography is recommended for patients receiving reperfusion therapy with fibrinolytic therapy. If the results of fibrinolytic therapy are found incomplete or unsuccessful, PCI is indicated. In patients receiving UFH, an additional bolus dose of UFH will likely be needed to achieve a therapeutic ACT as directed with primary PCI. If the patient is receiving enoxaparin, an additional 0.3-mg/kg intravenous bolus dose should be given if the last subcutaneous dose was more than 8–12 hours before PCI, similar to patients with NSTE ACS with an early invasive approach.1 As with other areas of PCI in ACS management, patients receiving fondaparinux need to receive UFH, with the dose depending on the additional use of a GP IIb/IIIa inhibitor.

ROLE OF THE PHARMACIST

Acute coronary syndromes represent a significant health burden to patients with CV disease. Patients should be aggressively treated to reduce future ischemic events and improve survival. The role of the pharmacist is more valuable than ever in ACS as the number of medication options increases and drug regimens become more complex. The pharmacist must consider the clinical characteristics of the patient experiencing an ACS event when selecting an agent and regimen and should monitor the safety and efficacy of medications. New pharmacologic controversies involving clinical response to medications, intensity and duration of therapies, drug-drug interactions, and adverse effects provide an opportunity for pharmacists to educate health care clinicians and further enhance patient care.

LEARNING OBJECTIVES

1. Discuss the epidemiology, etiology, and most common causes of cardiac arrest.

2. Define each component of the “chain of survival,” and apply this concept to a patient with cardiac arrest.

3. Discuss the importance of electrical defibrillation and its effect on survival for a patient with ventricular fibrillation (VF) or pulseless ventricular tachycardia (PVT).

4. Given an individual patient who presents with sudden cardiac arrest, develop an appropriate treatment plan for VF, PVT, pulseless electrical activity, or asystole depending on the underlying patient-specific cause.

5. Compare and contrast the different sympathomimetic agents used to treat VF or PVT.

6. Discuss the role of vasopressin for a patient with cardiac arrest.

7. Describe the role of antiarrhythmic agents in a patient with VF or PVT.

8. Describe the role of therapeutic hypothermia to optimize outcomes in patients with cardiac arrest.

9. Discuss treatment strategies that pertain to post-resuscitative care after a cardiac arrest.
10. Formulate a monitoring plan for the post-resuscitation phase of cardiac arrest.

**OVERVIEW OF SUDDEN CARDIAC DEATH/SUDDEN CARDIAC ARREST**

Introduction/Definitions
Sudden cardiac death (SCD) is defined by the World Health Organization as an unexpected death that occurs within 1 hour from symptom onset in a witnessed event, or within 24 hours from the last time the patient was observed as being alive and without symptoms in unwitnessed circumstances. A key aspect of the definition is the duration of symptoms preceding the terminal event. Although often interchanged with SCD, sudden cardiac arrest (SCA) is a distinct event. Sudden cardiac arrest is defined as the cessation of cardiac function leading to circulatory collapse that is reversed by cardiopulmonary resuscitation (CPR) or defibrillation. The cessation of cardiac mechanical activity as confirmed by the absence of signs of circulation (e.g., a detectable pulse, unresponsiveness, and apnea) in SCD typically occurs when a triggering activity takes place in vulnerable substrate that results in a life-terminating cardiac rhythm such as ventricular fibrillation (VF), pulseless electrical activity (PEA), or asystole. In many cases of SCA/SCD, preexisting heart disease may or may not have been known to be present, but the time and mode of death are unexpected. These definitions incorporate key elements of natural, rapid, and unexpected.

**Epidemiology of SCA**

Sudden cardiac death accounts for more than 50% of the deaths from cardiovascular disease; therefore, SCD/SCA represents a significant and challenging burden from a public health perspective. Current estimates are that 600,000 people in the United States experience SCA, and the survival rate for these events in the community is only 6%. Survival for in-hospital cardiac arrest is better, but still low at 24%. Unfortunately, these survival rates have not meaningfully improved during the past 30 years despite significant efforts at improving treatment options and public awareness. The estimates of SCA and SCD are challenging to ascertain, given the variability seen with different data sources, but death certificate data suggest that SCD accounts for 15%–20% of the total mortality in the United States and other industrialized countries. However, death certificate data may overestimate the prevalence of SCD. In a prospective evaluation of
deaths in one county in Oregon, SCD was implicated in 5.6% of annual mortality. As previously mentioned, despite advances in the management of coronary heart disease, the outcomes of patients with SCA are still suboptimal, although the prognosis varies significantly according to the initial rhythm and location of presentation. The risk of experiencing SCA is increased by several factors (see Table 34.1). For example, the incidence increases dramatically with age and with underlying cardiac disease. In addition, men are 2–3 times more likely than women to experience SCA. Among the 161,808 postmenopausal women who participated in the Women’s Health Initiative and were followed for an average of 10.8 years, the incidence rate of SCD was 2.4 per 10,000 women per year, and almost one-half of women who experienced SCD had no prior clinically recognized coronary heart disease.

**Etiology/Clinical Presentation**

Typical signs and symptoms of a patient presenting with SCD/SCA are consistent with lack of circulation because of the cessation of cardiac mechanical activity. Anxiety, crushing chest pain, nausea, vomiting, and diaphoresis can precede an arrest when the causative event is cardiac in nature. After an arrest, individuals are unresponsive and apneic, with no detectable pulse or blood pressure. Most SCD occurs in adults, with less than 1% of patients being younger than 35 years. Coronary heart disease is the most common cardiac pathology of SCD, affecting about 70%–75% of individuals, with the presence of underlying cardiomyopathies the second most common pathology at 10%–15%. The actual percentage may vary by sex and region of the world, though, with coronary heart disease being the primary underlying pathology in only 50% of women and an estimated 50%–60% of individuals in Japan. Unfortunately, in many patients (about two-thirds), cardiac arrest is the first clinical sign of coronary artery disease with no preceding signs or symptoms. In the adult population, cardiac arrest is typically the result of an underlying arrhythmia. Historically, VF and pulseless ventricular tachycardia (PVT) have been the most common initial rhythm,
accounting for 70% of SCAs, but their incidence is now 20%–25%.\textsuperscript{15} At the same time, the incidence of PEA or asystole as the first recorded rhythm has increased from 21% to 31% and from 17% to 28%, respectively, during the past 2 decades.\textsuperscript{15,16} The decline in VT/ventricular tachycardia (VF) and the increase in PEA and asystole as the initial rhythm identified in SCA may result from the confluence of several environmental, clinical, pharmacologic, or interventional factors. Several of these likely include the increasing role of implantable pacemakers and defibrillators in the treatment of patients with heart failure (HF), as well as the use of effective pharmacotherapy for HF such as angiotensin-converting enzyme inhibitors and β-blockers.\textsuperscript{15} Part of this changing pattern may also be because of an increased proportion of arrests occurring in the home, where the arrest is less likely to be witnessed. In addition, these patients are more likely to be older with several comorbidities that lead to precipitants of PEA (respiratory, metabolic, vascular) as opposed to VF or PVT.\textsuperscript{8} Nonetheless, this declining incidence is particularly troubling because survival rates are substantially higher with shockable rhythms such as VF and PVT than with non-shockable rhythms such as PEA and asystole. Survival rates with VF/PVT are 15%–23% versus 0%–5% with asystole.\textsuperscript{7}

</table>
GENERAL APPROACH TO MANAGEMENT

In patients with SCA/SCD, the ultimate goal is the long-term survival of a neurologically intact patient. Intermediate goals that facilitate this ultimate objective include (1) early CPR and defibrillation, (2) increased coronary perfusion pressure (CPP) and cerebral blood flow, (3) return of spontaneous circulation (ROSC), (4) survival to hospital admission, (5) stabilization of the patient, and (6) prevention of future SCD episodes. The 2010 American Heart Association (AHA) guidelines for CPR and emergency cardiovascular care emphasize high-quality CPR and attempted defibrillation for pulseless VT/VF, as well as advances in post-cardiac arrest interventions to optimize outcomes.6,17

A three-phase model for treating SCA from either VT or PVT highlights the impact of time on the likelihood of success for CPR of defibrillation. The model postulates that the first 5 minutes after an arrest is the electric phase, and rapid defibrillation should be a top priority because it will likely be successful at producing a perfusing rhythm. In fact, data analyses indicate that survival can exceed 60% with proper defibrillation in the electric phase. The second or circulatory phase takes place 5–10 minutes after SCA, and the delivery of chest compressions should take priority, followed by defibrillation. The supporting concepts are that chest compressions are necessary to restore some blood flow to the myocardium in this phase to increase the chances of successful defibrillation. The third or metabolic phase postulates that after 10 minutes, the use of chest compressions and defibrillation is insufficient to improve survival, and some form of metabolic resuscitation may be needed. Overall, the model highlights the need to quickly identify patients with SCA and provide life-saving interventions as soon as possible.15

Cardiopulmonary Resuscitation
Cardiopulmonary resuscitation is an attempt to restore spontaneous
circulation by performing chest compressions (to restore threshold blood flows, particularly to the heart and brain) with or without ventilations. Two theories exist on how CPR may restore some level of blood flow. The first, the cardiac pump theory, simply states that active compression of the heart between the sternum and the vertebrae creates forward flow. Echocardiography, however, has revealed that left ventricular size does not always change with compressions and that the mitral valve may, in fact, be open. The second, the thoracic pump theory, postulates that blood flow is restored through changes in intrathoracic pressure and the differential compressibility of the arteries and veins. In this model, the heart merely acts as a passive conduit for flow. However, both models likely contribute to the mechanism of blood flow with CPR.

An important consideration regarding survival is the quality of the CPR delivered because high-quality CPR continues to be emphasized in the latest AHA guidelines. Manual chest compressions should be delivered such that the sternum is depressed at least 2 inches 100–120 times per minute. The upper limit is a new recommendation based on one study showing that higher rates lead to inadequate chest compression. Ideally, half of the time is spent in compression, and interruptions in the delivery of compressions should be minimized. If ventilation is being delivered simultaneously, caution should be used not to overinflate the thoracic cavity. The delivery of suboptimal CPR is more common than desired, especially when rescuers are fatigued. Conversely, when high-quality CPR is delivered, the chance for survival is increased. Several devices are available that provide prompts and/or feedback in “real time”; however, data showing improvement in survival are lacking. In addition, mechanical devices designed to improve hemodynamics have been studied, but inconsistent results limit their applicability in routine practice.

The evolution of resuscitation techniques has a long history, with the first landmark article, released in 1960, describing the use of chest compressions and ventilation in 20 patients, with three patients receiving defibrillation for VF. All 20 patients had ROSC, with 14 patients surviving long term. Resuscitation techniques have been
studied for many years. Research began to accrue, and the AHA published the first guidelines for cardiac arrest in 1966. Resuscitation techniques have evolved over the years since culminating in the most recent guidelines, published in full in 2010 with updates provided in 2015. The “chain of survival” continues to be the focal point for the approach to treating SCA/SCD and continues to highlight the need for timely interventions. The 2010 guidelines, together with the 2015 update, list five links in the chain of survival:

1. Immediate recognition of cardiac arrest and activation of emergency medical services (EMS)
2. Early CPR with an emphasis on chest compressions
3. Rapid defibrillation
4. Effective advanced life support
5. Integrated post-cardiac arrest care

Although all five links in the chain of survival are important, the most crucial appear to be the first three, particularly early CPR with good chest compressions. The available literature supports this assessment because CPR has been shown to prolong the time VF is present as well as increase the chances that defibrillation will terminate VF. Successful defibrillation during witnessed VF arrests decreases rapidly from the onset of collapse, with survival rates decreasing 7%–10% per minute in the absence of CPR. If immediate CPR is added, the decrease in survival is more gradual, reduced to 3%–4% per minute after arrest onset. Additional studies have shown that when properly combined, CPR and defibrillations can increase survival rates above 50% of out-of-hospital cardiac arrest. Although CPR is critical to increase survival, it is unlikely to terminate VF alone and lead to restoration of a perfusing rhythm. As such, the 2010 AHA guidelines specifically emphasize the integration of early CPR and defibrillation, especially mentioning the use of automated external defibrillators (AEDs), which is reinforced in the 2015 update (see Figure 34.1). Although CPR and defibrillation are crucial, delivering advanced cardiac life support (ACLS) and effective post-resuscitative care is also a key
component in the chain of survival. In fact, the growing importance of post-arrest care reflects that optimizing many organ systems may help improve outcomes.29

Basic Life Support
The 2010 AHA guidelines, and subsequently the 2015 update, introduced major changes in recommendations for how basic life support should be delivered. The old pneumonic for rescuers—“ABC,” representing airway, breathing, and circulation—was replaced with “CAB,” representing circulation, airway, and breathing.30 The changes reflected the challenges of lay rescuers when trying to assess for respirations using the look, listen, and feel approach, as well as the potential for agonal respirations being mistaken for normal breathing. Assessing a pulse may also be challenging for a lay rescuer. As such, the guidelines were revised to ensure that rescuers delivered timely chest compressions and defibrillation, interventions that are known to increase survival. When first encountering a patient with presumed cardiac arrest, the initial action is to determine the patient’s responsiveness. If there is no response, the rescuer should immediately activate the emergency medical response system. Once emergency medical response is contacted, the rescuer should either secure or call for an AED and immediately start CPR with chest compressions. Health care providers at this point should assess for a pulse before CPR but take no more than 10 seconds to do so. If one is not detected within this short time, chest compressions should be initiated immediately.30 The importance of timely chest compressions has previously been highlighted, and the prompt provision of chest compressions (high-quality CPR) is thus of paramount importance and should be provided regardless of the rescuer’s skill or experience. The most recent basic life support algorithm calls for initiating CPR, with rhythm check every 2 minutes, shocking if indicated with an AED, with continued repetition. Once chest compressions have been initiated, a trained rescuer should incorporate rescue breaths into the process because opening the airway has the potential to improve oxygenation and allow for better attempts at ventilation. Rescue breaths and airway
management should in no way impede or delay the delivery of compressions and defibrillation, however. A trained rescuer can deliver rescue breaths, either by mouth to mouth or, preferentially, by bag-mask ventilation, delivering a breath over 1 second, using enough volume to elicit a visible chest rise and using a compression/ventilation ratio of 30:2.\textsuperscript{22,29} If no AED is available, cycles of chest compression and rescue breaths should continue (with pulse checks every 2 minutes) until the arrival of EMS or the ROSC. If an AED is available, the rhythm should be analyzed to determine whether defibrillation is advised (see Figure 34.1). If so, one shock should be delivered with the immediate resumption of chest compressions, followed by rescue breaths. The rhythm can be reevaluated and an additional shock delivered, if appropriate, after an additional 2 minutes of high-quality CPR plus rescue breaths. This algorithm should be repeated until help arrives or until the rhythm is no longer “shockable.” If the rhythm is not shockable, chest compressions and rescue breath cycles should be continued until help arrives or until the patient attains ROSC. Ongoing education of health care providers and especially the public is needed to continue to improve outcomes in SCA. The problem of poor-quality CPR being delivered was previously highlighted, and more importantly, only 20%–30% of adults with out-of-hospital cardiac arrest receive bystander CPR.\textsuperscript{30} This has led to further educational interventions in an attempt to increase the quality and delivery of CPR, and EMS dispatchers often try to give instructions over the telephone when EMS is activated. Recent data analyses have shown that delivering hands-only CPR is as effective at improving survival as delivering CPR combined with rescue breaths.\textsuperscript{30,31} This finding is important because bystanders are reluctant to consider mouth to mouth, although one data set cites panic as a reason not to pursue bystander CPR rather than actual reluctance.\textsuperscript{31}

**Advanced Cardiac Life Support**

The transition from basic life support to ACLS triggers the implementation of more advanced interventions. Advanced cardiac life support providers can use an advanced airway (endotracheal tube,
laryngeal mask airway) to more adequately provide ventilation to the patient. When this occurs, the rescuers no longer need to provide the cycles of 30:2 compression to ventilation. Instead, continuous chest compressions are recommended without pauses for ventilations, and the rescuer providing the ventilations needs to deliver a breath once every 6–8 seconds. If capable, ACLS providers may implement more advanced metrics of monitoring that may assist in determining the success of resuscitation efforts. The available literature suggests that the monitoring of end-tidal carbon dioxide (ETCO₂), CPP, and Scvo₂ (central venous oxygen saturation) can provide valuable information regarding the success of resuscitation, and the 2010 guidelines strongly recommend ETCO₂ monitoring during CPR if at all possible.²⁸

If the cardiac rhythm is deemed non-shockable, it is likely to be either asystole or PEA, and ACLS providers must quickly consider whether reversible causes are present (see Table 34.2). If the person is in VF or PVT, one shock should be delivered (appropriate to the available electrical device), with the immediate resumption of chest compressions (using 30 compressions to two breaths for five cycles, or 2 minutes of continuous compressions with assisted ventilations) before rechecking the rhythm or pulse. If there is still a shockable rhythm, one shock should be delivered, and at this time, pharmacologic intervention can be considered. Although drug therapy with primarily vasopressors and antiarrhythmic agents is still a recommended component of advanced resuscitation efforts, the current literature suggests that these interventions will have minimal impact on overall long-term survival (see Figure 34.1). Vasopressors are typically recommended to be initiated after a first unsuccessful attempt at defibrillation, with antiarrhythmic therapy an option for consideration after two failed attempts at defibrillation. Chest compressions for 2 minutes (five cycles of chest compressions to breaths) should be performed in between attempts at defibrillation. This algorithm will repeat until a pulse is obtained with effective circulation, the rhythm changes, or resuscitation efforts cease.²²,²⁸ Despite its limited role in improving outcomes compared with the delivery of high-quality CPR and defibrillation, drug therapy still has a role in ACLS, and pharmacists should be well versed
Drug Administration Considerations in Cardiac Arrest

Although specific medications such as vasopressors and antiarrhythmic agents play only a secondary role in the overall ACLS effort, ensuring the appropriate preparation of these agents together with appropriate dose and frequency of administration is an important consideration for the multidisciplinary cardiac arrest team. Properly trained pharmacists can perform any role on this team; however, managing crash cart medications and drug therapy overall is perhaps best suited for the skills a pharmacist can bring to this multidisciplinary team. Specific recommendations have been developed to define the role of pharmacists as part of the ACLS team, as well as the training needed for individuals to fulfill their role successfully. Appropriate training will allow pharmacists to anticipate drug therapy needs during the management of cardiac arrest and ensure that dose, frequency, and drug selection are appropriate according to the AHA guidelines. In addition, pharmacists who are members of an in-hospital cardiac arrest team can facilitate the gathering of pertinent information related to drug therapy administration in the field by emergency medical personnel (EMS). Drug therapy in the field typically will consist of routine ACLS medications but may also include more unique agents such as thrombolytic therapy for ST-elevation myocardial infarction (MI). Identifying the drugs, doses, and timing of doses delivered will facilitate the continuation of resuscitation efforts in the hospital.

Considerations regarding the route of administration to deliver medications include the ease of obtaining access, ability to effectively deliver drug therapy into the central circulation, and minimization of any interruptions in chest compressions during CPR. A peripheral intravenous line is often the easiest to attain during resuscitation attempts. Drug administered through this line can be followed by a 20-mL bolus of intravenous fluid and elevation of the arm to facilitate drug entry into the central circulation. Although delivering medication through a central line would be preferred with respect to attaining rapid access to the central circulation and at higher concentrations,
central line access during CPR is often not feasible. If a central line is already in place, it should be used for drug administration.\textsuperscript{33} Intraosseous cannulation is preferred if intravenous access is not available, and many studies have documented the success of this route in both the adult and pediatric populations.\textsuperscript{26,34} Pharmacokinetic data available indicate that similar responses occur with intraosseous and intravenous administration with respect to area under the curve and peak concentrations.\textsuperscript{35} Several devices are available to achieve rapid intraosseous access and can easily be placed on the first attempt more than 80\% of the time.\textsuperscript{33} If neither intravenous nor intraosseous access can be obtained, some medications can be administered through an endotracheal tube. These medications include epinephrine, vasopressin, lidocaine, atropine, and naloxone. No data currently exist with amiodarone. The absorption through alveoli is rapid, but this results in lower plasma concentrations when the same dose is administered intravenously. Therefore, when medications are given by the endotracheal route, a dose of 2–2.5 times the recommended intravenous dose should be used and diluted in 5–10 mL of sterile water or 0.9\% normal saline.\textsuperscript{33}

\textbf{MANAGEMENT OF SPECIFIC RHYTHM DISORDERS}

\textbf{Ventricular Fibrillation/Pulseless Ventricular Tachycardia}

\textbf{Nonpharmacologic Therapy—Defibrillation}
Electrical defibrillation is the only effective method of restoring a perfusing cardiac rhythm in either VF or PVT; therefore, it is a crucial link in the chain of survival, especially for a witnessed arrest.\textsuperscript{22,26} As previously discussed, the probability of successful defibrillation is directly related to the time interval between the onset of VF and the delivery of the first shock.\textsuperscript{26} In one study, each 1-minute reduction in the time to defibrillation resulted in a 23\% relative improvement in survival (odds ratio [OR] 0.77 [95\% confidence interval {CI}, 0.73–
As discussed previously, CPR delivery before defibrillation may increase the chances of success, especially if the time from arrest is greater than 5 minutes. For in-hospital cardiac arrest, if an AED is available, CPR should begin while the AED is being placed. With out-of-hospital cardiac arrest, there is growing evidence that CPR before defibrillation is beneficial. Clinical trials indicate that CPR before defibrillation increased ROSC, survival to discharge, and 1-year survival. In one trial, the provision of about 90 seconds of CPR before defibrillation was associated with an increased rate of hospital survival (27% vs. 17%; p=0.01). Higher survival rates were reported in patients with response intervals greater than 5 minutes when 3 minutes of CPR was administered before defibrillation (22% vs. 4%; p=0.006). Additional studies have indicated that total survival is increased when each defibrillation was preceded by 200 uninterrupted chest compressions (57% [19 of 33] vs. 20% [18 of 92], p=0.001) as well as neurologically normal survival (48% [16 of 33] vs. 15% [14 of 92], p=0.001). Finally, one study noted improved in-hospital survival (from 22% to 44%, p=0.0024) in patients with witnessed VF using a modified resuscitation protocol that included 200 preshock chest compressions. However, not all published studies support the premise of CPR before defibrillation. Given the overall positive results, the 2010 AHA guidelines and 2015 update continue to offer that EMS personnel may give 2 minutes of chest compressions before attempting defibrillation. Recommendations are similar for individuals in the metabolic phase, although the chances of achieving ROSC are much lower.

Figure 34.1 Adult cardiac arrest algorithm—2015 update.
The 2010 AHA guidelines and 2015 update continue to recommend one shock for VF or PVT with the immediate resumption of chest compressions.\textsuperscript{22,26} This revision from previous versions where stacked multiple shocks were initially given is largely because of the prolonged time noted (about 55 seconds) to deliver three stacked shocks without providing adequate chest compressions.\textsuperscript{42} The defibrillation attempt should be with 360 J (monophasic defibrillator) or 150–200 J (biphasic defibrillator). An AED, if available, should be used as soon as possible, with the electrode pads placed in an anterolateral position on the patient. After defibrillation is attempted, CPR should be immediately restarted and continued for 2 minutes without checking a pulse. The omission of the pulse check after defibrillation is again a paradigm shift in the algorithm that is related to myocardial stunning with resultant poor perfusion and diminished cardiac output immediately after electrical therapy.\textsuperscript{26} After 2 minutes of chest compressions, the rhythm and pulse should be rechecked. If there is still evidence of VF or PVT, repeat single-discharge defibrillation should be attempted with the addition of pharmacologic therapy. Once an airway is achieved, patients should be ventilated with 100% oxygen. Laryngeal mask airways and esophageal-tracheal combination tubes represent several available airway adjuncts, but the preferred airway is an endotracheal tube placed with direct laryngoscopy. Other interventions are also being evaluated as nonpharmacologic therapy. Additional nonpharmacologic therapy where there is evolving evidence includes placing a left ventricular assist device, performing angiography and percutaneous coronary intervention during suspected MI, and using ECMO (extracorporeal membrane oxygenation). These procedures have improved outcomes in some series, but the logistics of widespread implementation is daunting.\textsuperscript{43–45} Although there are no
conclusive human data regarding these interventions, they raise interesting concepts worthy of discussion and evaluation.

Pharmacologic Therapy

Vasopressors
No placebo-controlled trials have shown that administering vasopressors in SCA increases the rate of neurologically intact survival at discharge. However, the available evidence indicates that vasopressors can increase the rate of ROSC (see Table 34.3). As such, vasopressors continue to be the first pharmacologic agents administered in the setting of cardiac arrest. The primary goal of vasopressor therapy is to augment the low coronary and cerebral perfusion pressures encountered during CPR. Chest compressions can provide some degree of blood flow but only an estimated 25% of that encountered under basal conditions.\textsuperscript{46} When CPP remains below 15 mm Hg, the ROSC is unlikely, which is likely to be encountered even with properly performed chest compressions.\textsuperscript{47,48} Vasopressor therapy works to increase CPP and arterial pressure through its vasoconstrictive properties. Epinephrine and vasopressin are the two main vasopressor agents to consider, as stated in the 2010 AHA guidelines, although the 2015 update provides alternative recommendations on vasopressin that will subsequently be addressed.\textsuperscript{22} Other agents that are pure $\alpha_1$-agonists (phenylephrine and methoxamine) or agents with more potent $\alpha_1$ activity (norepinephrine) have also been investigated in the setting of SCA, generally compared with epinephrine, though. When pure $\alpha_1$-agonists were compared with epinephrine, no differences in long-term survival between the agents were noted.\textsuperscript{49–51} Comparisons between epinephrine and norepinephrine generally have not revealed differences in ROSC, survival to hospital admission, or, most importantly, long-term survival.\textsuperscript{52,53} Given the decades-long experience in managing SCA and the lack of strong outcome data suggesting that alternative catecholamine derivatives improve outcome, epinephrine continues to be a drug of first choice (together with vasopressin) for the treatment
of VF, PVT, asystole, and PEA. Epinephrine is an α- and β-receptor agonist causing both vasoconstriction and increased inotropic/chronotropic activity on the heart. Its effectiveness, however, is primarily through its α effects.\textsuperscript{54}

Although epinephrine is a first-line recommendation for pharmacologic therapy, few adequately randomized controlled trials evaluate it in the setting of out-of-hospital SCA versus placebo. Available evidence as such comes from less robust trial designs. In one study, patients were randomized to receive standard ACLS with intravenous drug administration or standard ACLS without intravenous drug administration.\textsuperscript{55} Of the 851 patients analyzed, VF/PVT was the initial rhythm in 34%. Intravenous medications administered included epinephrine (79%), atropine (46%), and amiodarone (17%). A significant increase in ROSC (40% vs. 25%, p<0.001) and hospital admission (43% vs. 29%, greater than p<0.001) was noted in patients who received intravenous therapy. This difference was primarily observed in patients with initial rhythms other than VF/PVT. The role of epinephrine in contributing to these outcomes was not assessed. In one small randomized controlled trial comparing epinephrine with placebo in 534 patients, ROSC (23.5% vs. 8.4%, p<0.001) and survival to hospital admission (25.4% vs. 13%, greater than p<0.001) were significantly higher with epinephrine, but there was no difference in survival to hospital discharge (4% vs. 1.9%, p=0.15).\textsuperscript{56} However, contrasting results were observed in one large prospective registry study of more than 400,000 patients, which failed to show a survival benefit with epinephrine.\textsuperscript{57} Despite a significant improvement in ROSC with epinephrine (adjusted OR [95% CI] 2.36 [2.22–2.5]), both 1-month survival (adjusted OR [95% CI] 0.46 [0.42–0.51]) and survival with good neurologic function (adjusted OR [95% CI] 0.31 [0.26–0.36]) were lower in patients who received epinephrine. These findings were confirmed through various sensitivity analyses accounting for in-hospital epinephrine use and CPR duration.

</tbody>
</table>
Comatose adult patients with ROSC after out-of-hospital VF cardiac arrest should be cooled to 32°C–34°C (89.6°F–93.2°F) for 12–24 hr. 

Induced hypothermia can be considered for comatose adult patients with ROSC after in-hospital cardiac arrest of any initial rhythm or after out-of-hospital cardiac arrest with an initial rhythm of PEA or asystole.

\[D_5W = \text{dextrose 5% in water} \quad \text{IO = intraosseous(ly)} \quad \text{LOE = level of evidence; PVT = pulseless ventricular tachycardia; ROSC = return of spontaneous circulation.}\]

Key for evidence-based classifications: Class of recommendations:

- **Class I**: High-level prospective studies support the action or therapy, and the benefit substantially outweighs the potential for harm. The treatment should be administered.
- **Class Ia**: The weight of evidence supports the action or therapy, and the therapy is considered acceptable and useful. It is reasonable to administer the treatment.
- **Class IIb**: The evidence documents only short-term benefits, or weakly positive or mixed results. Class IIb recommendations are identified by terms such as “may be useful” or “can be considered.”
- **Class III**: The risk outweighs the benefit for a particular treatment. The treatment should not be administered and may be harmful.

Levels of Evidence (LOEs):

- **Level A**: Data derived from multiple randomized clinical trials or meta-analyses
- **Level B**: Data derived from a single randomized trial or nonrandomized studies
- **Level C**: Only consensus opinion of experts, case studies, or standard of care

Disparate results for epinephrine may be related to its underlying pharmacology. Epinephrine causes $\alpha_1$-mediated vasoconstriction that increases coronary perfusion and may also promote ventricular defibrillation. But the same $\alpha_1$-mediated vasoconstriction may lead to decreased perfusion of other vital organs.\(^{58}\) In addition, $\beta_1$-agonist effects may lead to increased myocardial metabolic demands, impaired oxygen delivery, and increased lactate production in the post-resuscitation period.\(^{59}\)

Despite these potential concerns, the larger controversy during the past 10–15 years is the appropriate dose of epinephrine in the management of SCA. The rationale for higher doses (5–10 mg)
compared with standard doses is the lack of tissue responsiveness when acidosis is present. Three separate studies in the 1990s comparing high-dose epinephrine (7–10 mg or 0.2 mg/kg) with standard-dose epinephrine (1 mg) found no differences in immediate survival, ROSC, or survival to hospital discharge.\textsuperscript{52,60-61} A subsequent meta-analysis, however, found a higher ROSC with high-dose epinephrine, but no overall mortality benefit was seen.\textsuperscript{62} In the largest study to date with out-of-hospital SCA caused by VF, PEA, or asystole, 3,327 patients were randomized to a high-dose strategy (5 mg of epinephrine) versus a standard-dose strategy (1 mg).\textsuperscript{63} Repeated doses could be administered up to a total of 15 mg for epinephrine. The rates of ROSC and survival to hospital admission were higher in the high-dose strategy, but neurologic outcome and survival to hospital discharge were similar between groups. Despite the improving rate of ROSC in SCA in several trials, no studies have shown a difference in survival. Possible reasons include the post-resuscitation adverse effects associated with higher doses such as myocardial dysfunction, tachycardia, and hyper-tension. As such, a 1-mg dose of epinephrine administered by intravenous or intraosseous injection every 3–5 minutes during cardiac arrest is reasonable to consider.\textsuperscript{28} Higher doses may be administered to treat specific disorders such as β-blocker or calcium channel blocker overdose. In addition, higher doses can be considered if indicated through arterial diastolic pressure (or CPP) monitoring.

**Vasopressin**

Vasopressin, also known as antidiuretic hormone, is a neuropeptide hormone that increases blood pressure and systemic vascular resistance through potent vasoconstriction. The vasoconstrictive properties are primarily because of its effects on the V1 receptor. Stimulation of the V2 receptors on the renal collecting duct causes an antidiuretic effect and hence the name “antidiuretic hormone,” which vasopressin is sometimes called. As a potential initial option for vasopressor therapy, vasopressin has several theoretical advantages over epinephrine. The metabolic acidosis that often accompanies
cardiac arrest can blunt the vasoconstrictive effect of adrenergic agents such as epinephrine, but not with vasopressin. Vasopressin, because it does not act on β1-adrenergic receptors, lacks the potential to raise myocardial oxygen demand in the post-resuscitative phase. Vasopressin has a more gradual onset and sustained effect than epinephrine, leading, in theory, to sustained peripheral vasoconstriction. Vasopressin also may have a beneficial effect on renal blood flow by stimulating V2 receptors in the kidney, causing vasodilation and increased water reabsorption. With respect to splanchnic blood flow, however, vasopressin has a detrimental effect compared with epinephrine. Advancing the idea that vasopressin may improve outcomes in SCA compared with epinephrine is the fact that measuring the vasopressin levels in patients undergoing CPR has shown a high correlation between the levels of endogenous vasopressin released and the potential for ROSC. In fact, in one study, plasma vasopressin concentrations were about 3 times as high in survivors as in non-survivors, suggesting that vasopressin is released as an adjunct vasopressor to epinephrine in life-threatening events such as cardiac arrest. Vasopressin appeared in the resuscitation guidelines after 2000 after animal and small human studies appeared to confirm its potential to increase CPP, improving the ROSC.

Despite the favorable trajectory of vasopressin in the realm of SCA, clinical trials have not consistently shown superior results compared with epinephrine (see Table 34.4). Three large randomized trials that enrolled individuals with SCA to receive vasopressin 40 units intravenously × 1 dose or epinephrine 1 mg resulted in similar outcomes between the two groups with respect to ROSC, survival to discharge, and neurologic outcome. In one large trial of out-of-hospital arrest, no significant differences were noted in ROSC, hospital admission rate, or discharge rate. However, when patients were stratified according to their initial rhythm, those with asystole had a significantly higher rate of hospital admission (29% vs. 20%; p=0.02) and discharge (4.7% vs. 1.5%; p=0.04) with vasopressin than with epinephrine. In addition, a subgroup analysis of 732 patients who required additional epinephrine therapy despite the
two doses of study drug had significant benefits in ROSC (37% vs.
26%; p=0.002), hospital admission rate (26% vs. 16%; p=0.002), and
discharge rate (6.2% vs. 1.7%; p=0.002) with vasopressin. There was
a trend, however, toward a poorer neurologic state or coma among the
patients who survived to discharge and received vasopressin. A
systematic review and analysis was conducted stemming from the data
at the time looking at five randomized controlled trials comparing
vasopressin and epinephrine in SCA.\textsuperscript{74} No statistically significant
differences were observed between the two agents with respect to
ROSC, death, or neurologic impairment in survivors. Further subgroup
analysis by presenting rhythm also failed to show any differences
between vasopressin and epinephrine.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
\textbf{Investigative Trials with Vasopressin in Cardiac Arrest} & \\
\hline
\end{tabular}
\end{table}
Given the evidence to date, several investigations tested the hypothesis of combined therapy (vasopressin plus epinephrine) versus epinephrine alone.\textsuperscript{69,70} In one trial, patients who had received more than one dose of epinephrine during CPR for out-of-hospital SCA were randomized to vasopressin (40 units, n=167) or placebo (n=158). No differences were found between groups with respect to ROSC, nor was response according to initial cardiac rhythm different between groups.\textsuperscript{70} The second trial was also of patients with out-of-hospital arrest who were randomized to either successive doses of vasopressin 40 units and epinephrine 1 mg (n=1,442) or epinephrine 1 mg and placebo (n=1,452). No statistically significant differences in survival to
hospital admission were seen between the combination groups and the epinephrine-only group (20.7% vs. 21.3%), or in ROSC (28.6% vs. 29.5%), or survival to hospital discharge (37.5% vs. 51.5%). One study evaluated a multidrug regimen that also included corticosteroids for patients with in-hospital cardiac arrest. In this study, patients were randomized to receive either epinephrine alone or 20 units of vasopressin plus 1 mg of epinephrine and 40 mg of methylprednisolone (followed by hydrocortisone in the post-resuscitative phase). Vasopressin 20 units plus epinephrine 1 mg was repeated during each of four subsequent CPR cycles. This study marks the first to include corticosteroids as part of drug therapy during CPR. The rationale is based on the hemodynamic effects of steroids alone with their potential to affect the intensity of the post-resuscitation systemic inflammatory response and organ dysfunction. Significant benefits were observed in ROSC (81% vs. 52%, \( p=0.003 \)) and survival to hospital discharge (19% vs. 4%, \( p=0.02 \)) with combination therapy including corticosteroids. Future studies are required to determine the role of vasopressin and corticosteroids for cardiac arrest.

In lieu of the conflicting results across many randomized controlled trials, a meta-analysis was performed to further define the role of vasopressin. Six studies were chosen for analysis (four out-of-hospital arrests and two in-hospital arrests) including 4,745 patients. No significant improvements were noted with vasopressin therapy in ROSC (OR [95% CI] 1.25 [0.9–1.74]), long-term survival (OR [95% CI] 1.13 [0.71–1.78]), or favorable neurologic outcome (OR [95% CI] 0.87 [0.49–1.52]). When patients were stratified according to the presence of VF/PVT as their initial rhythm, the incidence of ROSC (OR [95% CI] 1.18 [0.82–1.69]) and long-term survival (OR [95% CI] 0.95 [0.66–1.37]) was similar with vasopressin. Of note, in patients with asystole, vasopressin was associated with superior long-term survival rates relative to control (OR [95% CI] 1.8 [1.04–3.12]).

In summary, existing evidence has not consistently shown an advantage of vasopressin to epinephrine in patients with SCA. As such, in the 2010 guidelines, one single dose of vasopressin 40 units given intravenously/intraosseously can be considered as an alternative to
either the first or the second dose of epinephrine. Because repeated
doses of vasopressin seem to lack benefit, they are not recommended.
However, one major change in the 2015 update was the removal of
vasopressin from the ACLS cardiac arrest algorithm recognizing the
equivalence of effects with epinephrine.\textsuperscript{22,28} This change is likely to
generate some controversy, given the data supporting the use of
vasopressin in SCA and the time and resources it may take to
effectively remove vasopressin as an option to use in SCA, including
the education of health care professionals. Although vasopressin is no
longer an option in the 2015 updated recommendations, the available
scientific data nonetheless support the recommendations in the 2010
guidelines. In addition, future prospective trials are needed to validate
the role of vasopressin in certain subpopulations (e.g., asystole) or
when combined with corticosteroids.

\textbf{Antiarrhythmics}
Administering antiarrhythmic agents is considered second line to using
vasopressor therapy after unsuccessful defibrillation attempts.
Conceptually, antiarrhythmic agents prevent the development or
recurrence of VF and PVT by raising the defibrillation threshold.
Despite their inclusion in the resuscitation guidelines, evidence is
lacking that using antiarrhythmic agents improves survival to hospital
discharge. Current guidelines recommend using a single agent, if
possible, to mitigate the potential for adverse effects if the patient is
resuscitated.\textsuperscript{76}

Historically, lidocaine was considered the preferred antiarrhythmic
agent for SCA because of its perceived lower risk of adverse events
compared with procainamide, as well as available animal studies
showing lidocaine’s ability to raise the defibrillation threshold and
prevent post-MI VF.\textsuperscript{33,77} Only one retrospective analysis associated
lidocaine use with improved hospital admission rates in patients with
out-of-hospital SCA.\textsuperscript{78} However, other published trials have not
identified a benefit for lidocaine with respect to ROSC, or survival to
hospital admission or discharge.\textsuperscript{77,79} Given the lack of evidence to
support a benefit for lidocaine to improve outcomes, it is currently
recommended only when amiodarone is not available.

Amiodarone is the recommended antiarrhythmic in patients with VF or PVT who are unresponsive to CPR, defibrillation, and vasopressor therapy. Amiodarone is useful for both atrial and ventricular arrhythmias because of its many actions on sodium, potassium, and calcium channels as well as its $\beta_1$-adrenergic receptors. Amiodarone is classified as a class III antiarrhythmic, but it has electro-physiologic characteristics of all four Vaughan Williams classifications. Available clinical trial data showing that amiodarone improves the rate of ROSC and survival to hospital admission make it the first-line antiarrhythmic agent in patients with SCA having VF or PVT.

Initial evidence supporting the use of amiodarone came in 1999 with publication of the ARREST trial.\textsuperscript{80} Five hundred four patients with out-of-hospital SCA secondary to VF or PVT were randomized in a double-blind fashion to receive either amiodarone 300 mg or placebo after having received epinephrine 1 mg and three unsuccessful defibrillation attempts. Recipients of amiodarone were more likely to be resuscitated and survive to hospital admission (44\% vs. 34\%, $p=0.03$), but there was no difference in survival to hospital discharge (13.4\% vs. 13.2\%, $p=\text{NS}$). A subsequent trial (known as the ALIVE trial) compared amiodarone 5 mg/kg with lidocaine 1.5 mg/kg in patients with out-of-hospital cardiac arrest caused by VF.\textsuperscript{81} After three unsuccessful defibrillations as well as a single dose of epinephrine (1 mg), followed by another defibrillation attempt, patients received randomized antiarrhythmic therapy. Amiodarone was associated with a relative improvement of 90\% in survival to hospital admission compared with lidocaine (22.8\% vs. 12\%; OR 2.17 [95\% CI, 1.21–3.83]; $p=0.009$). Similar to the ARREST trial, there was no difference in survival to hospital discharge (amiodarone 5\% vs. lidocaine 3\%; $p=0.34$). Survival to hospital admission was highly dependent on the time from initiation of resuscitation efforts, with amiodarone having no benefit over lidocaine when antiarrhythmic therapy was administered more than 24 minutes from initiation of resuscitation. Amiodarone and lidocaine have also been compared in patients after in-hospital cardiac arrest. In a multicenter, retrospective review, 194 patients with VF or PVT who
received amiodarone (n=74), lidocaine (n=79), or both (n=41) were evaluated. The survival rates at 24 hours were 55%, 63%, and 50% for patients receiving amiodarone, lidocaine, or both, respectively (p=0.39). There was no difference in survival to hospital discharge (amiodarone 39%; lidocaine 45%; both 42%; p=0.72). After adjusting for multiple covariates, Cox regression analysis revealed higher survival to 24 hours (hazard ratio [HR] [95% CI] 3.15 [1.68–5.92], p<0.001) and hospital discharge (HR [95% CI] 3.25 [1.22–8.65], p=0.02) in patients who received lidocaine than in those who received amiodarone. The mean initial dose of amiodarone, though, was 190 mg, and only 25% of patients received the recommended dose of 300 mg.

Adverse effects of amiodarone encountered in cardiac arrest include hypotension and bradycardia. Amiodarone’s adverse hemodynamic effects are primarily attributed to vasoactive solvents, namely polysorbate 80 and benzyl alcohol. A formulation of amiodarone exists that does not contain these solvents, and adverse hemodynamic effects appear to be minimized. Nevertheless, administering a vasoconstrictor before amiodarone can potentially prevent hypotension.

Amiodarone should be administered as a 300-mg bolus after unsuccessful defibrillation and the administration of one dose of epinephrine. A supplemental dose of 150 mg by intravenous bolus can be considered if resuscitation attempts are still unsuccessful. If ROSC is achieved, a 1-mg/minute intravenous infusion for 6 hours should be implemented, followed by a maintenance infusion of 0.5 mg/minute. If amiodarone is unavailable, lidocaine can be administered at a dose of 1–1.5 mg/kg. Additional doses of 0.5–0.75 mg/kg can be considered up to a maximum dose of 3 mg/kg if VF or PVT persists. If ROSC is achieved, a maintenance infusion of 1–4 mg/minute is recommended, with a reduction to 1–2 mg/minute in patients with underlying hepatic dysfunction.

Magnesium
Severe hypomagnesemia has been associated with VF/PVT, but routine administration of magnesium during a cardiac arrest has shown
no benefit in clinical outcome. Three randomized placebo-controlled trials failed to identify a benefit for magnesium to improve outcomes in SCA caused by VF in the prehospital, intensive care unit, or emergency department environments.\textsuperscript{84–86}

Two observational trials, though, have noted an improvement in ROSC in patients with arrests associated with torsades de pointes who received a 1- to 2-g bolus of magnesium by intravenous push.\textsuperscript{87,88} Therefore, magnesium administration should only be administered to these patients.

**Thrombolysis**
Myocardial infarction or pulmonary embolism is often the underlying cause for many SCAs because such thrombolytics have been evaluated during CPR in the management of SCA. Earlier smaller studies have shown some benefit with their use, but in the two largest randomized controlled trials, no difference was noted. In the first, 233 patients with PEA were randomized to receive either tissue plasminogen activator (tPA) or placebo.\textsuperscript{79} The proportion of patients with ROSC was 21.4\% and 23.3\% for tPA- and placebo-treated patients, respectively. There was no significant difference in hemorrhage rates. The second study randomized patients with out-of-hospital cardiac arrest to receive either tenecteplase or placebo.\textsuperscript{78} After a blinded review by the data and safety monitoring board, the criteria for futility were met, and enrollment was terminated. A total of 1,050 patients were analyzed, and both ROSC (tenecteplase, 55\% vs. placebo, 55\%; \textit{p}=0.96) and survival to hospital discharge (tenecteplase, 15.1\% vs. placebo, 17.5\%, \textit{p}=0.33) were similar between groups. Furthermore, the incidence of intracranial hemorrhage was significantly greater with tenecteplase than with placebo (2.7\% vs. 0.4\%, \textit{p}=0.006). Given these results, fibrinolytic therapy should not be used routinely in cardiac arrest; however, when pulmonary embolism is presumed (or known) to be the cause, fibrinolytics can be considered.\textsuperscript{22}

**Therapies with No Role or Potential Harm**
Sodium bicarbonate has historically been used to correct acidosis in
the setting of SCA. Cardiac arrest produces acidemia secondary to low blood flow and hypoxemia. Important considerations include that acidosis impairs receptor responsiveness to adrenergic agents, may impair defibrillation, impairs myocardial contractility, and reduces the rate of ROSC and short-term survival. As such, it was thought that correcting acidosis using buffering agents might improve outcomes. However, using sodium bicarbonate during resuscitation efforts is now recognized to have no positive effect and may, in fact, have deleterious effects. One prospective randomized controlled trial of 502 patients with out-of-hospital cardiac arrest secondary to VF or asystole provided mixed results. Administering 250 mL of a buffer solution resulted in no improvements in ROSC or survival to discharge. A second prospective controlled trial of 874 out-of-hospital patients with SCA administered a 1-mEq/kg dose of bicarbonate or placebo showed no difference in survival in the trial overall; however, in patients with prolonged arrest (greater than 15 minutes), there was a trend for increased survival (32.8% vs. 15.4%) with bicarbonate administration. In contrast, several data sources suggest that bicarbonate administration results in worse outcomes. Exogenous administration of sodium bicarbonate has several potential disadvantages, including inducing extracellular alkalosis, exacerbating alkalemia, and inhibiting the release of oxygen. It may also lead to hyperosmolality and hypernatremia. Given these potential drawbacks and the preponderance of data suggesting harm, the routine use of sodium bicarbonate is strongly discouraged. However, sodium bicarbonate may still be considered in specific situations, which will be discussed later.

Outside the management of hyperkalemia, the exogenous administration of calcium in the management of SCA is rarely needed. Clinical trials have found variable effects on ROSC, and no trials have shown a benefit on survival either to hospital admission or to discharge. As such, routine administration is not recommended. Although atropine is present in previous versions of the ACLS guidelines, the 2010 update withdrew atropine as a recommendation in the management of VF/PVT. Removal was based on the lack of any high-
quality evidence defining a benefit for atropine in SCA.\textsuperscript{33}

**PEA and Asystole**

Pulseless electrical activity is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT. Available studies indicate that patients with PEA actually have mechanical cardiac contractions, but they are too weak to produce a palpable pulse or blood pressure. Although PEA is still classified as a “rhythm of survival,” the success rate of treatment is much lower than the rates seen with VF/PVT.\textsuperscript{94} Asystole is commonly the end-stage terminal rhythm that is observed in attempted but unsuccessful resuscitation for VF/PVT or PEA. It is typically viewed as a confirmation of death as opposed to a rhythm to be treated, given that the survival rate is only 1 or 2 patients in 100.

**Nonpharmacologic Therapy**

Both PEA and asystole are considered non-shockable rhythms, and when they are identified in the course of resuscitation, high-quality CPR should be resumed immediately for 2 minutes before checking a rhythm again. Although defibrillation has no role in managing these rhythms, the most important intervention in PEA arrest is to identify and treat the underlying cause. Many conditions that inhibit effective cardiac contraction may lead to PEA arrest, and correcting these conditions is vital to improving survival. Suspected causes should be investigated while the patient receives high-quality CPR. The “Hs and Ts” (see Table \textsuperscript{34.2}) are the most common causes of PEA/asystole arrest, and if identified, rapid management of these conditions should ensue. Airway management should also be a priority in managing asystole/PEA arrest, given that hypoxemia is likely an underlying factor.\textsuperscript{22,28,33}

**Pharmacologic Therapy**

**Vasopressors**

The primary pharmacologic agents that can be considered in treating asystole or PEA are epinephrine and vasopressin, although similar to
patients with VT/VF, the use of vasopressin is no longer recommended in PEA/asystole according to the 2015 AHA guideline update. Although no studies evaluate these therapies solely in patients with asystole or PEA, these rhythms represent those of most patients included in clinical trials. In an observational trial where the first documented rhythm was PEA or asystole, epinephrine was associated with a significant improvement in ROSC, but 1-month survival and survival with good neurologic function were lower with epinephrine. In contrast, in a subgroup analysis of a randomized controlled trial comparing epinephrine with placebo, higher rates of ROSC and survival to hospital admission were observed with epinephrine in patients with non-shockable rhythms.

Vasopressin has also had variable results in currently available studies. In a post-hoc subgroup analysis of patients with out-of-hospital arrest and asystole as the first identified rhythm, survival rates to hospital admission (29% vs. 20%, p=0.02) and discharge (4.7% vs. 1.5%, p=0.04) were significantly higher with vasopressin than with epinephrine. There was, however, a nonstatistically significant increase in coma/vegetative state with vasopressin (40% vs. 0%, p=0.14). Similar findings were cited in a meta-analysis of randomized controlled trials comparing vasopressin with control. Patients with asystole who were administered the study drug within 20 minutes had higher rates of ROSC (OR [95% CI] 1.7 [1.17–2.47]) and long-term survival (OR [95% CI] 2.84 [1.19–6.79]). However, one randomized controlled trial that evaluated combination therapy with vasopressin and epinephrine reported no advantage with vasopressin in patients with asystole. In fact, a post-hoc subgroup analysis of patients with PEA as the initial rhythm showed a lower survival rate (0% vs. 5.8%, p=0.02) with combination therapy than with epinephrine alone.

Similar to the management of VF/PVT, epinephrine 1 mg intravenously/intraosseously is recommended in the management of PEA/asystole. In the 2010 AHA guidelines, vasopressin 40 units intravenously/intraosseously could replace the first or second dose of epinephrine, although as previously mentioned, this is removed from the 2015 update. However, as in VT/VF, the scientific literature available
would still support vasopressin as an option for use.\textsuperscript{22,28}

**Atropine**
Similar to the management of VF/PVT, one agent that is no longer recommended in the setting of PEA or asystole is atropine.\textsuperscript{28} Atropine is an antimuscarinic agent that blocks the depressant effect of acetylcholine on both heart rate and atrioventricular nodal conduction, thus decreasing parasympathetic tone. No prospective controlled trials show benefit from atropine for the treatment of asystole or PEA, and conflicting evidence exists across retrospective and observational reports. Therefore, atropine should not routinely be administered in this setting.

**Acid/Base**
As discussed previously, sodium bicarbonate was once given routinely to reduce the detrimental effects associated with acidosis (e.g., reduced myocardial contractility), enhance the effect of epinephrine, and improve the rate of defibrillation, but few clinical data support its use, and in fact, routine use maybe harmful.\textsuperscript{89,96} Sodium bicarbonate can be used in special circumstances, which may more likely be encountered with PEA/asystolic arrest (i.e., underlying metabolic acidosis, hyperkalemia, salicylate overdose, or tricyclic antidepressant overdose); however, the dosage should be guided by laboratory analysis, if possible. Tromethamine (THAM) is an alternative buffering agent that acts as a proton acceptor, but there is a dearth of clinical experience with this agent in cardiac arrest, and outcome studies are not currently available.\textsuperscript{28}

---

**POST-RESUSCITATION CARE**

**General Measures**
During the past decade, there has been increasing recognition that systematic post-cardiac arrest care is vital to increasing the likelihood of survival and increasing quality of life.\textsuperscript{29} Survivors of SCA have a high
mortality rate within the first 24 hours as the unstable myocardium tries to mitigate any ischemia and reperfusion injury. As patients convalesce beyond 24 hours, they are susceptible to sepsis and multiorgan dysfunction that may lead to shock, all the while being at risk of SCA recurrence. The four main components of postcardiac arrest syndrome highlighting succinct pathophysiologic processes and potential areas for treatment include postcardiac arrest brain injury, myocardial dysfunction, systemic ischemia/reperfusion response, and persistent precipitating pathology. Management of multiorgan dysfunction and potential central nervous system injury during post-arrest care has the potential to reduce mortality. After ROSC, adequate airway and oxygenation must be ensured. Additional post-arrest measures include appropriate fluid resuscitation and correction of electrolyte and acid-base imbalances. Appropriate intensive care unit measures include raising the head of the bed to 30 degrees (if this can be tolerated hemodynamically) to reduce the risk of aspiration, ventilator-associated pneumonia, and cerebral edema. Because the most common cause of cardiac arrest is ischemia, a rapid search for electrocardiographic (ECG) changes consistent with acute MI should be undertaken as soon as possible in the post-arrest time interval. If an acute MI is present, urgent revascularization should be enacted immediately. Hemodynamic instability may be present post-arrest, necessitating the implementation of vasoactive drug therapy to improve cardiac output and/or address inappropriate vasodilation. Few data exist regarding which vasoactive agents are preferred in the post-cardiac arrest period. Reasonable goals for adequate hemodynamic status include a mean arterial pressure greater than 65 mm Hg and a venous oxygen saturation greater than 70%.

**Therapeutic Hypothermia**
Targeted temperature management has become a vital intervention to improve outcomes in patients who are resuscitated from SCA but remain comatose. Temperature elevations after SCA can impair neurologic recovery, potentially through the release of inflammatory cytokines. Restoring blood flow after cardiac arrest can lead to several
chemical cascades and destructive enzymatic reactions that can result in cerebral injury. These reactions include free radical production, excitatory amino acid release, and calcium shifts, which ultimately lead to mitochondrial damage and apoptosis.\textsuperscript{99} Case series and clinical studies that showed an association between pyrexia of 37.6°C and higher and worsening survival laid the foundation for investigating induced hypothermia as a therapeutic intervention in SCA survivors. Hypothermia can protect from cerebral injury by suppressing these chemical reactions, thereby reducing the production of free radicals.\textsuperscript{33} Various animal models have shown improved functional recovery and reduced cerebral deficits with the induction of mild therapeutic hypothermia.\textsuperscript{100}

The first success with hypothermia was described in two pivotal trials.\textsuperscript{101,102} In the first study, resuscitated patients after VF cardiac arrest who remained comatose were randomized to undergo therapeutic hypothermia, targeting a temperature of 32°C–34°C (89.6°F–93.2°F), for 24 hours or no intervention.\textsuperscript{101} The primary end point was neurologic outcome within 6 months of cardiac arrest. Secondary end points were mortality (within 6 months) and complication rate within 7 days. A favorable neurologic outcome was achieved in 55% of patients in the hypothermia group as opposed to 39% in the normothermia group (p=0.009). In addition, mortality rates were improved significantly in the hypothermia group (41% vs. 55%; p=0.02). The incidence of complications (e.g., bleeding, pneumonia, sepsis, and renal failure) did not differ between the two groups (73% for the hypothermia group and 70% for the normothermia group; p=0.70). Entry criteria in the second trial were similar to those in the previous trial, but the target temperature for hypothermia was 33°C (91.4°F), which was maintained for 12 hours.\textsuperscript{102} The primary outcome measure was survival to hospital discharge with good neurologic function. Forty-nine percent of patients in the hypothermia group had good neurologic function on discharge (either to home or to a rehabilitation facility) compared with 26% of patients in the normothermia group (p=0.046). Mortality rates were similar between the two groups (51% for the hypothermia group and 68% for the
normothermia group; \( p = 0.145 \)). Hypothermia was associated with a lower cardiac index, higher systemic vascular resistance, and hyperglycemia.

Data on therapeutic hypothermia have continued to accumulate since the publication of these landmark trials. These include studies of arrests caused by rhythms other than VF. Two nonrandomized trials found benefit for therapeutic hypothermia in improving neurologic function in patients presenting with PEA/asystolic arrest.\(^{103,104}\) An additional study showed that therapeutic hypothermia (combined with percutaneous coronary intervention, tight glycemic control, and seizure control) doubled the 1-year survival rate (reportedly with good brain function) from 26% to 56%.\(^{105}\) The implementation of therapeutic hypothermia in clinical practice (i.e., outside the context of a clinical trial) has also been evaluated. A review of this topic found significant variation in reported protocols but showed that survival and neurologic outcomes benefit from post-arrest hypothermia and “are robust when compared over a wide range of studies of actual implementation” (OR [95% CI] 2.5 [1.8–3.3]).\(^{106}\) No method for achieving targeted temperature control has been shown to be the most appropriate for use. Main methods currently in use include cold-water immersion, endovascular cooling catheters, and surface-cooling devices.\(^{29}\) After the cooling period, patients should undergo a controlled rewarming period at 0.5°C–1°C every hour until normal core temperature is reached.

After a review of the available data to date, the current guidelines recommend that unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest be cooled to 32°C–36°C for at least 24 hours.\(^{29,107}\) This is particularly true of VF arrest (class I recommendation; level of evidence B). There is less robust evidence for other arrests, but according to the guidelines, hypothermia should be considered for comatose adult patients with ROSC after in-hospital cardiac arrest with any rhythm and/or out-of-hospital cardiac arrest with an initial rhythm of PEA (class IIb recommendation; level of evidence B).

Pharmacists play an important role in optimizing outcomes with
patients receiving therapeutic hypothermia post-SCA. Ensuring that adequate analgesia and sedation therapy is being provided as well as that neuromuscular blocking agents are being used appropriately are areas where pharmacists can have a direct impact on optimizing care. Several complications such as coagulopathy, dysrhythmias, hyperglycemia, increased incidence of pneumonia, and sepsis may occur as a result of induced hypothermia, and appropriate interventions should be at the forefront of daily assessment and development of pharmacotherapy plans for these patients. In addition, hypothermia can have profound effects on drug distribution and elimination.\textsuperscript{108} Although the duration of hypothermia is typically short, careful monitoring during this period is necessary, particularly with vasoactive agents.

CONCLUSIONS

Despite the available treatments for patients with SCA, survival remains low. Interventions that prevent the occurrence of SCA in the first place are likely the most effective means of reducing mortality. When SCA occurs, high-quality CPR is crucial to the success of any subsequent ACLS interventions. In patients with VF/PVT as the initial cardiac rhythm, defibrillation should be implemented rapidly with minimal interruptions to chest compressions in order to optimize outcomes. In the setting of unsuccessful defibrillation attempts, pharmacologic therapy can increase the ROSC and survival to hospital admission but, unfortunately, does not translate to improved long-term survival. Implementing high-quality post-arrest care, including therapeutic hypothermia, increases the likelihood of long-term survival with good neurologic recovery.

LEARNING OBJECTIVES

1. Describe features, epidemiology, pathophysiology, etiologies, risk factors, and morbidity and mortality associated with sinus bradycardia and atrioventricular (AV) blocks.

2. Design patient-specific drug therapy and/or nonpharmacologic treatment plans for critically ill patients with sinus bradycardia or AV blocks.

3. Describe features, epidemiology, pathophysiology, etiologies, risk factors, and morbidity and mortality associated with paroxysmal supraventricular tachycardias (PSVTs).

4. Describe and differentiate between AV node reentrant tachycardia, AV reciprocating tachycardia, and atrial tachycardia.

5. Design patient-specific drug therapy and/or nonpharmacologic treatment plans for critically ill patients with PSVT without preexcitation.

6. Design patient-specific drug therapy and/or nonpharmacologic treatment plans for critically ill patients with PSVT with preexcitation.

7. Describe features, epidemiology, pathophysiology, etiologies, risk factors, and morbidity and mortality associated with atrial fibrillation (AF).
8. Design patient-specific drug therapy and/or nonpharmacologic treatment plans for critically ill patients with AF.

10. Describe features, epidemiology, pathophysiology, etiologies, risk factors, and morbidity and mortality associated with monomorphic ventricular tachycardia (VT) with a pulse.

11. Design patient-specific drug therapy and/or nonpharmacologic treatment plans for critically ill patients with monomorphic VT with a pulse.

12. Describe features, epidemiology, pathophysiology, etiologies, risk factors, and morbidity and mortality associated with torsades de pointes (TdP).

13. Design patient-specific drug therapy and/or nonpharmacologic treatment plans for critically ill patients with TdP.

**Box 35.1. Class of Recommendation and Levels of Evidence**

In tables and figures, references are made to class of recommendation and levels of evidence. Those are defined as follows:

- Class I, IIa, IIb, or III = class of treatment recommendation from evidence-based and/or expert consensus-based treatment guidelines.
- Class I: Benefit >>> Risk; procedure/treatment should be administered.
- Class IIa: Benefit >> Risk; It is reasonable to perform procedure/administer treatment.
• Class IIb: Benefit ≥ Risk; Procedure/treatment may be considered.
• Class III: Risk ≥ Benefit: Procedure/treatment should not be performed/administered because it is not helpful and/or may be harmful.
• LOE = Level of evidence from evidence-based and/or expert consensus-based treatment guidelines.
• LOE A – Multiple populations evaluated; data derived from multiple randomized clinical trials or meta-analyses.
• LOE B – Limited populations evaluated; data derived from a single randomized trial or nonrandomized studies.
• LOE C – Very limited populations evaluated; only consensus opinion of experts, case studies, or standard of care.

SUPRAVENTRICULAR ARRHYTHMIAS

Bradycardias

Features
Normal heart rate is generally defined as 60–100 beats/minute. Sinus bradycardia is defined as a heart rate less than 60 beats/minute with otherwise normal sinus rhythm (Figure 35.1). Atrioventricular (AV) node block (also known as AV block) is defined as delay in impulse conduction in the AV node or the bundle of His. Atrioventricular block is categorized as first, second, or third degree, depending on the location of the conduction delay and the electrocardiogram (ECG) manifestation. First-degree AV block is defined as a PR interval greater than 0.2 second with 1:1 AV conduction (Figure 35.2). Second-degree AV block occurs when a proportion of impulses are not conducted through the AV node to the ventricles. Second-degree AV block occurs
in two primary patterns. Mobitz type I second-degree AV block (also known as Wenckebach) is defined as a repeating pattern with a constant PP interval but with a progressively prolonging PR interval until the impulse resulting in atrial depolarization (represented by the P wave) fails to be conducted through the AV node to the ventricles (Figure 35.3). Mobitz type II AV block is defined as a consistent PR interval until the impulse resulting in atrial depolarization (represented by the P wave) abruptly fails to be conducted (Figure 35.4). Third-degree AV block, also known as “complete heart block,” represents AV dissociation, during which the AV node is impermeable to impulse conduction. Therefore, atrial and ventricular depolarization/contraction occur independently (Figure 35.5). QRS complexes may be narrow, reflecting block within the AV node, or wide, reflecting conduction block in the His-Purkinje system.

![Figure 35.1 Sinus bradycardia.](image)

**Figure 35.2** First-degree atrioventricular block.

**Figure 35.3** Second-degree atrioventricular block, Mobitz type I (Wenckebach).

Epidemiology
Prevalence of the disease known as “sick sinus syndrome,” which is associated with sinus bradycardia, is about 1 in 600 individuals older than 65 years.\(^1\) Prevalence of Mobitz type II second-degree AV block is about 0.003%.\(^2\) Prevalence of third-degree AV block is about 0.02%–0.04% in the general adult population.\(^2,3\) In a study encompassing 1991–1998, sinus node dysfunction accounted for 13.2% of hospital discharges associated with arrhythmias in older adult patients; third-degree AV block accounted for 5.8%, and Mobitz type I second-degree AV block accounted for 1.4%.\(^4\)

Clinically relevant bradycardia, excluding transient episodes, accounts for about 10% of the arrhythmias in patients in intensive care units (ICUs).\(^5,6\) Of bradycardia episodes occurring in ICUs, third-degree AV block constitutes about 31%, with the remainder including asystole (28%), sinus bradycardia (6%), second-degree AV block (6%), junctional bradycardia (6%), and various others.\(^5\)
Pathophysiology
Sick sinus syndrome resulting in sinus bradycardia occurs because of the development of fibrotic tissue in the sinoatrial node, replacing normal sinoatrial node tissue.\(^1\) Idiopathic AV block may be caused by degenerative changes within the AV node.

![Figure 35.5](image)

**Figure 35.5** Third-degree atrioventricular block (AV dissociation).

AV = Atrioventricular

Etiologies
Sinus node dysfunction may occur as a result of disease or drug therapy. Disease-associated sinus bradycardia may occur as a result of myocardial ischemia or myocardial infarction (MI), particularly involving the right coronary artery, a branch of which provides blood supply to the sinus node (and the inferior wall of the left ventricle); hypothyroidism; heart failure (HF); hypothermia; pericarditis; infiltrative diseases such as sarcoidosis, amyloidosis, or hemochromatosis; increased intracranial pressure; neurocardiac syncope; carotid sinus hypersensitivity; autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, or scleroderma; electrolyte imbalances such as hypo- or hyperkalemia; myotonic muscular dystrophy; surgical trauma such as during valve replacement, heart
transplantation, or correction of congenital heart disease; and vasovagal responses during coughing, micturition, defecation, or vomiting. In critically ill patients, bradycardia associated with hyperkalemia is not uncommon.\textsuperscript{6} Other causes of sinus bradycardia in patients in the ICU can include sleep apnea, increased intracranial pressure, and enhanced parasympathetic activity during endotracheal suctioning or emesis.\textsuperscript{6}

Idiopathic degeneration of the sinus node can occur with aging, sometimes leading to the condition known as sick sinus syndrome. In some cases, sick sinus syndrome occurs as a result of familial sinus node disease because of mutations in genes encoding cardiac sodium channels, the hyperpolarization activated “funny” ($I_f$) current, and others. Drug therapy that may cause sinus bradycardia includes adrenergic $\beta$-receptor blockers ($\beta$-blockers); non-dihydropyridine calcium channel blockers (diltiazem, verapamil); amiodarone; dronedarone; flecainide; propafenone; sotalol; digoxin; clonidine; anesthetics such as dexmedetomidine, halothane, ketamine, and propofol; and several others.\textsuperscript{7}

Similar to sinus node dysfunction, AV block may be caused by diseases or drug therapy. Atrioventricular block may occur as a result of myocardial ischemia or MI; infiltrative diseases such as sarcoidosis and amyloidosis; Hodgkin diseases; multiple myeloma; infectious processes such as Chagas disease, myocarditis, rheumatic fever, and endocarditis; rheumatic diseases such as rheumatoid arthritis, scleroderma, and Reiter syndrome; neuromuscular diseases such as myotonic muscular dystrophy; electrolyte disturbances such as hypo- or hyper-kalemia; surgical trauma; and accidental damage during catheter ablation. Drug therapy that may cause AV block includes $\beta$-blockers, diltiazem, verapamil, amiodarone, dronedarone, adenosine, flecainide, propafenone, sotalol, digoxin, clonidine, paclitaxel, and several others.\textsuperscript{7} Atrioventricular block occurring in ICU patients can be a result of sleep apnea, increased intracranial pressure, or enhanced parasympathetic activity during endotracheal suctioning, emesis, or endoscopy.\textsuperscript{6}
Morbidity and Mortality
First-degree AV block does not usually result in bradycardia and is therefore rarely symptomatic. Bradycardia caused by sinus node dysfunction or second- or third-degree AV block can result in dizziness, fatigue, light-headedness, syncope, chest pain (in patients with underlying ischemic heart disease), and shortness of breath and other symptoms of HF (in patients with underlying left ventricular dysfunction). The average lengths of ICU stay and hospital stay in older adult patients with a principal hospital discharge diagnosis of sinus node dysfunction are 1.1 days and 5.3 days, respectively; for those with a discharge diagnosis of third-degree AV block, 1.5 days and 5.6 days, respectively; and for those with a discharge diagnosis of Mobitz type I second-degree AV block, 1.1 days and 4.8 days, respectively. Bradycardia is rarely a direct cause of mortality.

Treatment
The potential for drug-induced sinus brady-cardia or AV block must be considered. If the patient is receiving therapy with any drugs that may cause bradycardia, they should be discontinued. A treatment algorithm for management of bradycardia is presented in Figure 35.6. Symptomatic or hemodynamically unstable bradycardia should be managed acutely with intravenous atropine, which increases heart rate by anticholinergic activity. Several studies have reported that atropine improves heart rate and associated symptoms in patients with sinus bradycardia and/or AV block. In a study of 61 patients with bradycardia associated with MI (n=32 with sinus bradycardia, n=29 with AV block or junctional rhythm), atropine administration increased the heart rate from 46 ± 14 beats/minute to 79 ± 12 beats/minute (p<0.001). In a small study in which 15 patients received atropine for intraoperative bradycardia (defined as heart rate less than 50 beats/minute or less than 60 beats/minute with a concomitant decrease in blood pressure), atropine increased heart rate to 70 beats/minute or more in a mean time of 270 seconds (range 30–490). However, response to atropine is not universal. Brady et al. assessed the response to atropine administered prehospital by emergency medical services personnel in
131 patients with bradycardia (AV block, n=45; sinus bradycardia, n=35; junctional bradycardia, n=38; idioventricular bradycardia, n=13). Complete response associated with atropine (defined as heart rate greater than 60 beats/minute and return of systolic blood pressure to greater than 90 mm Hg) occurred in 27.5%; partial response (defined as transient increase in heart rate to greater than 60 beats/minute and systolic blood pressure greater than 90 mm Hg, or an increase in heart rate of 10 or more beats/minute or systolic pressure of 10 mm Hg or greater that was either transient or maintained) occurred in 19.8% of patients. In 49.6% of patients, there was no response, whereas an adverse response (development of more than six ventricular premature depolarizations per minute or development of ventricular tachycardia [VT] or ventricular fibrillation) occurred in 2.3%. Atropine should be administered in doses of 0.5 mg intravenously every 3–5 minutes to a maximum recommended dose of 3 mg. In patients with symptomatic or hemodynamically unstable bradycardia unresponsive to atropine, and in whom transcutaneous or transvenous pacing is unavailable or ineffective, or while awaiting placement of a pacemaker, alternative drug therapy includes dopamine 2–10 mcg/kg/minute, titrated to response, or epinephrine 2–10 mcg/minute, titrated to response. Dopamine and epinephrine increase heart rate through agonism of adrenergic β1-receptors. Atropine, dopamine, and epinephrine should be used cautiously in patients with myocardial ischemia or MI because increasing heart rate and myocardial oxygen demand may enhance ischemia and extend the infarct.
Bradycardia (with pulse) requiring treatment

Identify and treat underlying cause
Discontinue drugs that may be causing/contributing

Maintain airway, assist breathing as necessary
Oxygen (if hypoxic)
Cardiac monitor to assess rhythm, monitor blood pressure and oximetry
Obtain IV access
12-lead ECG if available

- Hypotension
- Acutely altered mental status
- Shock
- Ischemic chest discomfort
- Acute heart failure

OR
Dopamine infusion\textsuperscript{c}
OR
Epinephrine infusion\textsuperscript{c}

If ineffective

Consider:
Expert consultation
Transvenous pacing\textsuperscript{c}

Assess need for permanent pacemaker
Temporary transcutaneous or transvenous pacing may be used to maintain an adequate heart rate until underlying etiologies for bradycardia can be corrected or a permanent pacemaker, when necessary, can be implanted. Long-term management of sick sinus syndrome or AV block that is not associated with correctable conditions requires implantation of a permanent pacemaker.

If symptomatic or hemodynamically unstable bradycardia is because of a presumed or documented overdose of β-blockers, appropriate treatment with intravenous glucagon, calcium, and/or hyperinsulinemia-euglycemia (HIE) therapy may be initiated. Glucagon may be administered as an intravenous bolus dose of 3–10 mg (0.05–0.15 mg/kg), followed by a continuous infusion of 3–5 mg/hour (0.05–0.10 mg/kg/hour), titrated to achieve an adequate hemodynamic response. Evidence supporting the efficacy of glucagon for management of β-blocker overdose is derived primarily from case reports. Calcium 0.3 mEq/kg may be administered, either as calcium gluconate (10%) 0.6 mL/kg or calcium chloride (10%) 0.2 mL/kg over 5–10 minutes, followed by an infusion of 0.3 mEq/kg/hour. Although recommended, evidence supporting calcium infusion for β-blocker overdose is
somewhat limited.⁹ Some evidence suggests that HIE is a reasonable option for patients with β-blocker overdose and shock refractory to other treatments.⁹ Hyperinsulinemia-euglycemia may be administered as regular insulin 1-international unit/kg bolus followed by continuous infusion of 0.5–1 international units/kg/hour. The infusion dose may be titrated every 30 minutes to achieve the desired response. Because of the potential for insulin-associated electrolyte shifts, close monitoring of serum electrolyte concentrations during HIE therapy is recommended. Intravenous dextrose 25 g may be administered with the initial insulin bolus to maintain euglycemia (blood glucose 100–250 mg/dL), followed by continuous dextrose infusion at 0.5 g/kg/hour.⁹,¹³ In refractory cases of β-blocker or calcium channel blocker overdose, lipid emulsion infusions have been administered with some success.⁹,¹⁴,¹⁵

If symptomatic or hemodynamically unstable brady-cardia is because of a presumed or documented overdose of diltiazem or verapamil, evidence supporting the efficacy of specific antidotes is lacking.⁹ Several case reports describe administration of HIE for management of calcium channel blocker overdose and suggest that HIE, at doses described previously, is a reasonable therapeutic option.⁹ More limited evidence, also from case reports, is available to support calcium administration for management of calcium channel blocker overdose; calcium administration may be considered for patients with calcium channel blocker overdose and shock that are refractory to other treatments.⁹ Evidence is insufficient to recommend glucagon for management of calcium channel overdose.⁹

**Paroxysmal Supraventricular Tachycardia (AV node reentrant tachycardia, AV reciprocating tachycardia [including Wolff-Parkinson-White {syndrome} {WPW}], atrial tachycardia)**

**Features**
The term paroxysmal supraventricular tachycardia (PSVT) refers to a group of arrhythmias that require atrial or AV nodal tissue for their
initiation and maintenance.\textsuperscript{16} Arrhythmias included within the term PSVT include AV node reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), and atrial tachycardia (AT).\textsuperscript{17} In patients with AVNRT or AVRT, heart rates are 150–250 beats/minute, and the rhythm is regular.\textsuperscript{18} Heart rates in patients with focal AT are typically 150–250 beats/minute, whereas in multifocal atrial tachycardia, heart rates are generally 100–150 beats/minute.\textsuperscript{18} Focal AT is a regular rhythm; multifocal AT is irregular, but it can be distinguished from atrial fibrillation (AF) by the presence of P waves, which are absent in AF.\textsuperscript{18} A rhythm strip depicting AVNRT, the most common form of PSVT, is provided in Figure 35.7.

![Figure 35.7](image)

**Figure 35.7** Atrioventricular nodal reentrant tachycardia.

**Epidemiology**

The incidence of PSVT is about 35 cases per 100,000 individuals annually; the prevalence of PSVT is about 2.25 per 1,000 individuals.\textsuperscript{19} Atrioventricular node reentrant tachycardia constitutes about 60\% of PSVT cases.\textsuperscript{16} Around 30\% of PSVT cases are AVRT, with the remaining 10\% occurring because of AT.\textsuperscript{16} Atrial tachycardia can be focal or multifocal.

The onset of AVNRT can occur at any age, but it occurs most often during the fourth or fifth decades of life.\textsuperscript{20} In one analysis, the mean
age of onset of PSVT was 57 years.\textsuperscript{18} Atrioventricular reciprocating tachycardia commonly occurs in pediatric populations.\textsuperscript{20}

Around 0.1\%–2\% of patients hospitalized in ICUs develop PSVT.\textsuperscript{21–23} Paroxysmal supraventricular tachycardia accounts for about 7\% of arrhythmias occurring in ICUs and for about 8\% of tachyarrhythmias occurring in ICUs.\textsuperscript{5}

\textbf{Pathophysiology}

Atrioventricular node reentrant tachycardia has traditionally been thought of as a reentrant arrhythmia occurring within the AV node, which is functionally divided into two pathways. In most patients, antegrade AV nodal conduction occurs through the slower pathway, and retrograde conduction from ventricles back to atria occurs through the faster pathway.\textsuperscript{17} In a small proportion of patients (5\%–10\%), conduction occurs in the opposite direction, where antegrade conduction occurs over the fast pathway and retrograde conduction occurs over the slow pathway.\textsuperscript{17} However, it is now recognized that in many patients, a component of the reentrant circuit may exist outside the AV node in perinodal tissue.\textsuperscript{17}

Atrioventricular reentrant tachycardia is an arrhythmia in which one pathway of the reentrant circuit is within the AV node, and the other involves an accessory pathway, which is an extranodal pathway that connects the atria and ventricles across the ridge that separates atria from ventricles.\textsuperscript{17} In 90\%–95\% of patients with AVRT, conduction during the arrhythmia is orthodromic, with antegrade conduction through the AV node and retrograde conduction through the accessory pathway;\textsuperscript{16} conduction in the opposite direction is called antidromic. Perhaps the best-known condition that can lead to AVRT is WPW, the accessory pathway for which is known as the bundle of Kent. In patients with WPW, preexcitation is demonstrated on an ECG during sinus rhythm, which is evidence of ante-grade conduction by the accessory pathway.\textsuperscript{16} The degree of preexcitation evident on the ECG depends on the relative conduction from the atria to the ventricle through the AV node as opposed to via the accessory pathway.\textsuperscript{17}

Focal AT occurs as a result of regular atrial activation from a single
atrial focus; multifocal AT occurs as a result of atrial activation from multiple foci.\textsuperscript{17}

**Etiologies**
Paroxysmal supraventricular tachycardia is often idiopathic, occurring in relatively young individuals with no history or evidence of structural heart disease. Atrial tachycardia may occur in patients with congenital or acquired heart disease. Atrioventricular reciprocating tachycardia may occur in patients with accessory pathways because of hypertrophic cardiomyopathy or Ebstein's anomaly.\textsuperscript{17} Atrial tachycardia may be precipitated by drugs such as β-receptor agonists including albuterol and terbutaline; excessive use of caffeine; theophylline; or digitalis glycoside toxicity.\textsuperscript{7}

**Risk Factors**
About two-thirds of patients who develop PSVT are female.\textsuperscript{19} Age older than 65 years and female sex are independent risk factors for PSVT.\textsuperscript{19} Other risk factors for PSVT have not been identified.

**Morbidity and Mortality**
Symptoms associated with PSVT are related primarily to heart rate and include palpitations, dizziness, and light-headedness. Other symptoms can include shortness of breath and chest pain. Around 15% of patients have syncope.\textsuperscript{17} If rapid PSVT persists for weeks to months, a reversible tachycardia-induced cardiomyopathy may result.\textsuperscript{24} The average lengths of ICU stay and hospital stay in older adult patients with a principal hospital discharge diagnosis of PSVT are 0.8 days and 4.2 days, respectively.\textsuperscript{4}

Wolff-Parkinson-White syndrome is associated with sudden cardiac death in 0.15%–0.39% of patients.\textsuperscript{16} Sudden cardiac death in WPW usually occurs in patients who also have AF, which may be initiated by rapid AVRT. If AF develops in patients having WPW with an accessory pathway with a short antegrade refractory period, AF can result in a rapid ventricular response that may degenerate into ventricular
fibrillation. Patients with WPW who are at increased risk of sudden death include those with very short (less than 250 milliseconds) preexcited RR intervals during AF, multiple accessory pathways, history of symptomatic tachycardias, and Ebstein’s anomaly.

**Treatment**

Paroxysmal supraventricular tachycardia that is hemodynamically unstable, or for which adenosine therapy is not desired, should be treated with synchronized direct current cardioversion (DCC). If time permits, the patient should be sedated for cardioversion. The initial recommended DCC dose is 50–100 joules (J) biphasic shock for a regular PSVT; if irregular, the dose should be 120–200 J biphasic shock, or 200 J monophasic shock.

For patients with AVNRT that is hemodynamically stable, vagal maneuvers should be administered in an attempt to terminate the arrhythmia before initiation of drug therapy. Vagal maneuvers stimulate parasympathetic nervous system activity, increasing serum acetylcholine concentrations, which inhibits AV nodal conduction, facilitating termination of the arrhythmia. Vagal maneuvers alone may terminate PSVT in up to 25% of cases. The simplest vagal maneuver in a conscious patient is cough, which stimulates the vagus nerve. Unilateral carotid sinus massage may also be tried; however, carotid sinus massage should not be done in patients with a history of stroke or transient ischemic attack, or in those in whom carotid bruits are detected on auscultation. Conscious patients can also be instructed to do the Valsalva maneuver, during which one bears down against a closed glottis. If vagal maneuvers are unsuccessful at restoring sinus rhythm, or if they only transiently restore sinus rhythm, drug therapy should be administered subsequently.

Intravenously administered AV node-inhibiting drugs are the primary pharmacologic option for termination of AVNRT. In patients with AVNRT, AV node-inhibiting drugs interrupt the AV node reentrant circuit and terminate the arrhythmia. Drugs that may be used for termination of hemodynamically stable AVNRT are presented in Table 35.1. Adenosine, which is the drug therapy of choice, should be administered
after vagal maneuvers have failed. Adenosine directly inhibits AV node conduction and successfully terminates AVNRT in about 90% of patients. Adenosine is also sometimes administered to assist with the diagnosis of narrow QRS complex tachycardias. If the rhythm is AVNRT, adenosine administration usually terminates the arrhythmia; if the arrhythmia is atrial flutter, AV nodal inhibition by adenosine often slows the rate of the arrhythmia enough to uncover the typical flutter waves. Carotid sinus massage may also be used for this purpose.

Drugs for the termination of hemodynamically stable AVRT are presented in Table 35.2. In patients with AVRT and preexcitation, adenosine should be avoided because it may provoke AF with a rapid ventricular response. Algorithms for managing PSVT without preexcitation and PSVT with preexcitation are presented in Figure 35.8 and Figure 35.9.

Long-term management of AVNRT and AVRT consists primarily of catheter ablation, which is considered first-line therapy.

Atrial Fibrillation

Features
Atrial fibrillation is a supraventricular tachyarrhythmia characterized on ECG by absence of distinct repeating P waves, an undulating baseline representing chaotic atrial electrical activity, and an irregularly irregular rhythm (Figure 35.10). During AF, atrial depolarization is not occurring, and therefore, coordinated atrial contraction is absent. Paroxysmal AF is defined as that which terminates spontaneously or with intervention within 7 days of onset and is associated with recurring episodes of variable frequency and duration. Persistent AF is continuous AF that lasts longer than 7 days. Long-standing persistent AF is continuous AF that lasts longer than 12 months. The term permanent AF is applied when the patient and clinician arrive at a joint decision to terminate further attempts to reestablish and/or maintain sinus rhythm. In about 50% of patients with acute AF in the ICU, the rhythm spontaneously reverts to normal sinus rhythm within 48 hours.
Epidemiology

Atrial fibrillation is often described as the most common arrhythmia encountered in clinical practice. Estimates regarding the prevalence of AF in the United States (U.S.) in 2010 were 2.7–6.1 million patients.\textsuperscript{28,29} The prevalence of AF is expected to continue to rise and to reach 5.6–12 million patients by 2050.\textsuperscript{29} The prevalence of AF increases with advancing age. In individuals 50–59 years of age, the prevalence of AF is about 0.5%, doubling with each subsequent decade to a prevalence of about 9% in individuals 80–89 years of age.\textsuperscript{30} The incidence of AF in men ranges from 20.6 per 100,000 people 15–44 years of age to 1,077 per 100,000 in those 85 years and older.\textsuperscript{2} In women, the incidence of AF is 6.6 per 100,000 from 15 to 44 years of age and 1,204 per 100,000 in those 85 years and older.\textsuperscript{2} About 45% of patients with AF are men.\textsuperscript{2}

Atrial fibrillation is a common arrhythmia in critically ill patients. The overall incidence of AF in patients during stays in medical ICUs and/or surgical ICUs is 7.2%–10.5%.\textsuperscript{21,22,31,32} New-onset AF in medical ICUs/surgical ICUs occurs in 4.5%–7.2% of patients.\textsuperscript{22,31,32} New-onset AF associated with sepsis AF occurs in 4%–14% of patients.\textsuperscript{33–35} The incidence of AF increases according to the severity of sepsis; in one analysis, the incidence of new-onset AF was 8% (range 0%–14%), 10% (4%–23%), and 23% (6%–46%) in patients with sepsis, severe sepsis, and septic shock, respectively.\textsuperscript{35}

</table>
Atrial fibrillation occurs commonly after thoracic surgery. The incidence of AF after coronary artery bypass graft (CABG) surgery is 30%–47%\(^{36-39}\), the incidence is in the lower end of that range in patients undergoing isolated CABG and higher in patients undergoing both CABG and valve replacement surgery. Atrial fibrillation also occurs commonly in patients undergoing noncardiac thoracic surgery, specifically pulmonary resection and esophagectomy. The incidence of AF after pulmonary resection is 12%–30% after lobectomy and 23%–67% after pneumonectomy.\(^{40,41}\) Atrial fibrillation occurs in 13%–46% of patients after esophagectomy.\(^{41,42}\) The average time of onset of AF after both CABG and noncardiac thoracic surgery is 2–3 days.\(^{43,44}\)

**Pathophysiology**

Atrial fibrillation occurs as a result of structural and/or electrophysiological abnormalities that provoke abnormal impulse formation in the atria or pulmonary veins and subsequent impulse
propagation by atrial reentry.\textsuperscript{26} Atrial fibrillation requires a trigger for initiation, which is most commonly ectopic impulses generated in the left atrial myocardial sleeves that extend back into the pulmonary veins. Once triggered, AF is propagated by several simultaneously active atrial reentrant circuits associated with increased dispersion of atrial conduction and refractoriness.

**Etiologies**
Etiologies of AF include conditions/diseases that promote atrial hypertrophy, fibrosis, dilation, ischemia, or infiltration. Inflammation and oxidative stress may play a role in development of AF, as well as activation of the autonomic nervous system and the renin-angiotensin-aldosterone system. Several risk factors for AF exist, which contribute to these etiologies.

Drugs may provoke AF.\textsuperscript{7,45} It has long been recognized that heavy alcohol intake is associated with AF. Consumption of 35 or more drinks per week was associated with a hazard ratio for AF of 1.45 (1.02–2.04) in men.\textsuperscript{46} Drugs that could contribute to new-onset AF in ICU patients include adenosine, dobutamine, aminophylline, milrinone, and high-dose methylprednisolone administered in pulse doses.\textsuperscript{45}

**Risk Factors**
Risk factors for AF include older age, hypertension, diabetes mellitus, MI, valvular heart disease, HF, obesity, obstructive sleep apnea, smoking, and hyperthyroidism.\textsuperscript{26} Some genetic variants have been associated with AF, and familial clusters of AF have been identified, indicating that, for some patients, a genetic predisposition to AF may exist.\textsuperscript{26}

In critically ill patients with sepsis, risk factors for development of new-onset AF include older age, white race, acute organ dysfunction, mechanical ventilation, admission to the ICU, right heart catheterization, diagnosis of endocarditis, presence of a respiratory tract infection, and CABG surgery.\textsuperscript{35,47} In patients with severe sepsis, additional risk factors for new-onset AF include obesity, HF, metastatic or hematologic malignancy, prior stroke, respiratory failure, renal failure, hematologic
failure, abdominal or skin or soft tissue infection source, primary bacteremia, and infection with gram-positive bacteria or fungus. Factors associated with a lower risk of new-onset AF in patients with severe sepsis include female sex, black or Hispanic race, hypertension, diabetes mellitus, acidosis, and urinary tract source of infection. Reasons for these factors associated with a lower risk of new-onset AF in patients with severe sepsis are unknown.

Risk factors for AF after CABG surgery include age older than 60 years, male sex, previous AF, PR interval greater than 200 milliseconds, diabetes mellitus, hypertension, and left ventricular ejection fraction less than 40%. A risk score for prediction of post-CABG AF has been developed using these risk factors; each risk factor receives 1 point, with the exception of age older than 60 years (2 points) and history of AF (3 points). The risk of AF after bypass surgery using this risk score is as follows: score = 0–1: AF risk 7.5%–8.5%; score = 2: AF risk 12%–20%; score = 3: AF risk 20%–28%; score = 4: AF risk 33%–34%; score = 5: AF risk 40%–45%; score of 6 or higher: AF risk 42%–67%. In addition, some patients may have a genetic predisposition to develop postoperative AF; several SNPs (single nucleotide polymorphisms) have been independently associated with post-CABG AF. However, incorporating genetic information into the earlier-mentioned AF risk score did not improve its performance. Preoperative plasma concentrations of B-type natriuretic peptide (BNP; greater than 31 pg/mL) and N-terminal-proBNP (NT-proBNP; greater than 74 pg/mL) are predictive of the development of post-CABG AF.

Risk factors for AF after noncardiac thoracic surgery include lobectomy, bilobectomy, pneumonectomy, resection of mediastinal tumor or thymectomy, and esophagectomy; segmentectomy and multiple wedge resections were not associated with an increased risk of postoperative AF. Other independent risk factors for AF after noncardiac thoracic surgery include male sex, age 50–59 years, age older than 60–69 years, age 70 years and older, history of HF, history of arrhythmias, history of peripheral vascular disease, and intraoperative transfusions. Independent risk factors for AF occurring after pulmonary resection for lung cancer include pneumonectomy,
bilobectomy, older age, male sex, and clinical stage II or greater. Preoperative plasma BNP concentration greater than 30 pg/mL and preoperative plasma NT-proBNP concentration greater than 113 pg/mL are independent risk factors for AF after noncardiac thoracic surgery. A prediction rule for AF after major noncardiac thoracic surgery was developed and includes male sex (1 point), preoperative heart rate of 72 beats/minute or greater (1 point), age 55–74 years (3 points), and age 75 years or older (4 points). The risk of postoperative AF ranges from 0% (0 points) to 55% (6 points).

Morbidity and Mortality
Symptoms of AF are generally related to heart rate and include palpitations, dizziness, fatigue, light-headedness, shortness of breath, syncope, and exacerbation of HF symptoms. If the heart rate is sufficiently rapid, patients may be hemodynamically unstable with hypotension, acute chest pain, and/or cardiogenic shock. Atrial fibrillation is associated with a 2- to 7-fold increase in the risk of stroke, depending on the presence of other stroke risk factors. Atrial fibrillation is also associated with an increased risk of thromboembolism events other than stroke. The risk of new HF is increased about 3-fold in patients with AF. Atrial fibrillation is associated with a doubling in the incidence of dementia and a doubling in the risk of overall mortality.

Hemodynamic instability occurs in 37% of patients who develop new-onset AF in an ICU. Around 10% of patients with preexisting AF who develop AF in the ICU are hemodynamically unstable. New-onset AF in critically ill patients doubles the length of ICU stay as well as the total duration of hospital stay. In-hospital mortality and 60-day mortality are significantly greater in critically ill patients who develop new-onset AF. Atrial fibrillation in critically ill patients may be associated with thromboembolism; in one study of 108 ICU patients who developed supraventricular arrhythmias (79% of which were AF), 12 patients (11%) developed arterial thromboembolic events. These events included five strokes, three mesenteric infarctions, two limb ischemia, and two MIs.

In critically ill patients with sepsis, AF is associated with prolonged
duration of ICU stay, prolonged duration of total hospital stay, and a higher risk of ICU mortality, in-hospital mortality, and 28-day mortality. In addition, patients with sepsis who develop AF have a higher risk of requiring mechanical ventilation and a subsequently longer duration of mechanical ventilation. In patients with severe sepsis, AF is associated with an increased risk of in-hospital stroke and in-hospital mortality.

Post-CABG AF is associated with symptoms, hypo-tension, HF, increased need for inotropic medications, acute kidney injury, increased use of the intra-aortic balloon pump, prolonged ventilation, readmission to the ICU, and increased need for tracheostomy. In addition, post-CABG AF is associated with an increased risk of perioperative stroke. Post-CABG AF leads to prolonged length of ICU, step-down unit, and total hospital stay. Furthermore, AF is the most common cause of hospital readmission after CABG surgery. Post-CABG AF is associated with an increased risk of short- and long-term mortality.

Atrial fibrillation after noncardiac thoracic surgery is associated with symptoms, hemodynamic instability, and stroke. Atrial fibrillation after noncardiac thoracic surgery is associated with increased duration of ICU and total hospital stays and higher use of health care resources. Post-noncardiac thoracic surgery AF is associated with an increased risk of postoperative mortality, though it is unclear whether the mortality is directly associated with AF or whether AF is a marker for more severe illness.

Table 35.2 Drugs for Ventricular Rate Control in Critically Ill Patients with Atrial Fibrillation
Contraindicated in patients with Wolff-Parkinson-White syndrome or other preexcitation syndromes.

Avoid in patients with QTc interval > 440 ms (> 500 ms in patients with ventricular conduction abnormalities).

Treatment
A broad scheme for management of AF in the critically ill patient is presented in Figure 35.11. Atrial fibrillation that is hemodynamically unstable resulting in hypotension, acutely altered mental status, signs of shock, ischemic chest discomfort, or acute HF should be treated with synchronized DCC. If time permits, the patient should be sedated...
for cardioversion. The initial recommended DCC dose is 120–200 J biphasic shock or 200 J monophasic shock.\(^8\)

The goals of drug therapy for AF in critically ill patients are ventricular rate control, conversion to sinus rhythm, and prevention of thromboembolism. Drug therapy options for ventricular rate control for critically ill patients with AF are presented in Table 35.2 and include \(\beta\)-blockers, diltiazem, verapamil, digoxin, and amiodarone, all administered intravenously. Intravenous \(\beta\)-blockers have been shown to be effective for achieving ventricular rate control in patients with acute AF.\(^{62–64}\) Diltiazem was effective in controlling ventricular rate in 83% of patients with acute AF.\(^{65}\) The efficacy of \(\beta\)-blockers and calcium channel blockers for acute ventricular rate control is about equivalent,\(^{62–64}\) though diltiazem may achieve ventricular rate control more rapidly than metoprolol.\(^{64}\) Intravenous diltiazem was found to achieve ventricular rate control in a higher proportion of patients with acute AF than digoxin or amiodarone, and rate control was achieved in a shorter time with diltiazem than with digoxin or amiodarone as well.\(^{66,67}\) Intravenous diltiazem achieves ventricular rate control significantly more rapidly than intravenous verapamil and may also be associated with less propensity to cause profound hypotension.\(^{68}\) Digoxin administered alone is not a particularly effective agent for ventricular rate control in patients with acute AF, and its onset of action is slow, requiring several hours.\(^{26,67,69}\) Intravenous amiodarone has been shown to be more effective than digoxin for lowering ventricular rate in patients with acute AF, but it is not as effective as intravenous diltiazem.\(^{66,70}\) A treatment algorithm for ventricular rate control in patients with acute AF is presented in Figure 35.12, which is based on treatment guidelines for AF not associated with surgery,\(^{26}\) post-CABG AF,\(^{26}\) and AF after noncardiac thoracic surgery.\(^{44}\) If adequate ventricular rate control cannot be achieved using maximally tolerated doses of drugs administered as recommended in Figure 35.12, combinations of drugs may be used. For example, unless patients have acute decompensated HF and/or heart failure with reduced ejection fraction (HFrEF), the combination of digoxin and \(\beta\)-blockers or calcium channel blockers can be used, keeping in mind that there is a drug
interaction between verapamil and digoxin requiring administration of about 50% of the usual digoxin dose.
For patients with AF and WPW or other preexcitation syndromes, administration of diltiazem, verapamil, digoxin, or amiodarone is contraindicated because these drugs can accelerate the ventricular rate. In this situation, intravenous procainamide or ibutilide should be administered to slow the ventricular rate or restore sinus rhythm.26

Drug therapy options for conversion of AF to sinus rhythm in critically ill patients, which are presented in Table 35.3, include ibutilide, dofetilide, flecainide, propafenone, and amiodarone. These drugs slow atrial conduction velocity and/or prolong atrial refractoriness, promoting disruption of reentrant circuits and restoration of sinus rhythm.

A treatment algorithm for conversion of AF to sinus rhythm is presented in Figure 35.13. Within each category, there is no designated first-line drug therapy; medications should be selected on the basis of usual time required for AF conversion, adverse effect profile, and other patient-specific considerations. Direct current cardioversion is generally more effective than drugs for conversion of AF to sinus rhythm. However, patients who undergo elective DCC must
be sedated and/or anesthetized to avoid the discomfort associated with delivery of an electrical shock to the chest. Therefore, it is important that patients undergoing elective DCC not eat within about 8–12 hours before the procedure to avoid aspiration of stomach contents during the period of sedation/anesthesia. This must be considered when deciding whether to administer elective DCC or drug therapy for conversion of AF to sinus rhythm. If a patient presents with AF requiring nonemergency conversion to sinus rhythm and the patient has eaten a meal that day, pharmacologic conversion must be performed, or DCC must be postponed to the following day to allow for a period of fasting before the procedure.

Dofetilide is effective for conversion of AF to sinus rhythm in up to 30% of patients (compared with the 1.2% efficacy rate associated with placebo).\textsuperscript{71} About 70% of dofetilide-associated AF conversions occur within 24 hours, and about 25% require 36 hours.\textsuperscript{71} The primary adverse effect associated with dofetilide is torsades de pointes (TdP), which occurs in about 0.8% of patients with normal left ventricular function and about 3.3% of patients with HFrEF.\textsuperscript{72} To minimize the risk of TdP, the dofetilide dose should be carefully adjusted in patients with chronic kidney disease or acute kidney injury (see Table 35.3). Ibutilide is effective for the conversion of AF to sinus rhythm in 30%–50% of patients.\textsuperscript{73,74} The average time to conversion to sinus rhythm after ibutilide administration is 27 minutes.\textsuperscript{74} The primary adverse effect associated with ibutilide is TdP, which occurs in up to 8% of patients.\textsuperscript{74} However, the incidence of TdP in patients requiring one dose of ibutilide 1 mg is only 1.7%–2.5%; the TdP incidence rises when a second dose of 1 mg is administered.\textsuperscript{74} A single oral dose of flecainide or propafenone has been shown to be effective for restoration of sinus rhythm.\textsuperscript{75,76} In outpatients with AF, this approach is successful at terminating AF in 58%–94% of patients, depending on the duration of AF. The average time to conversion is 110–287 minutes.\textsuperscript{75,76} The efficacy of this approach in hospitalized critically ill patients is unknown, but it may be reasonable to try this approach in patients who can take oral medications and who do not have contraindications to flecainide or propafenone (Table 35.3; Figure 35.13). Intravenous amiodarone may
be effective for conversion of AF to sinus rhythm, with conversion times of 8–24 hours.\textsuperscript{77}

Anticoagulation of hospitalized critically ill patients with AF is desirable but may be challenging because many critically ill patients may have absolute or relative contra-indications to anticoagulation.\textsuperscript{78} Critically ill patients may be at increased risk of anticoagulation-associated bleeding as a result of several factors, including stroke, hemorrhage, thrombocytopenia, acute kidney injury, liver failure, acute respiratory distress syndrome, trauma, and recent surgery.\textsuperscript{78} Therefore, decisions regarding anticoagulation should be made with careful consideration of the potential benefits versus risks. For a critically ill patient with a history of AF who is experiencing AF in the ICU and who was receiving outpatient therapy with oral anticoagulation, anticoagulation should be continued whenever possible and appropriate. It may be reasonable to discontinue oral anticoagulation and initiate intravenous heparin or subcutaneous low-molecular-weight heparin therapy during the hospitalization. For critically ill patients with new-onset AF, the decision regarding the need for long-term anticoagulation will likely be deferred to postdischarge follow-up. During the period of hospitalization, anticoagulation is desirable if the bleeding risk is acceptable.

**Figure 35.10** Atrial fibrillation.

Patients with AF that is hemodynamically unstable should undergo immediate DCC (Figure 35.11), after which anticoagulation should be initiated in appropriate patients. Anticoagulation should be considered for patients with hemodynamically stable AF as well, particularly for patients undergoing elective DCC. If AF has been present for longer than 48 hours, anticoagulation should be initiated for patients with an acceptable bleeding risk. Bridging therapy with unfractionated heparin or low-molecular-weight heparin is recommended for patients with AF...
and a mechanical heart valve undergoing procedures requiring interruption of oral anticoagulation. For patients with AF less than 48 hours’ duration and high risk of thromboembolism who require conversion to sinus rhythm, intravenous unfractionated heparin, subcutaneous low-molecular-weight heparin, or a factor Xa or direct thrombin inhibitor is recommended as soon as possible before or immediately after cardioversion, followed by long-term anticoagulation. For patients with AF less than 48 hours’ duration who are at low risk of thromboembolism, intravenous heparin, subcutaneous low-molecular-weight heparin, a new oral anticoagulant, or no antithrombotic may be considered for cardioversion, with no need for postcardioversion anticoagulation. For patients with AF greater than 48 hours’ duration who require conversion to sinus rhythm, conversion to sinus rhythm should be deferred if an atrial thrombus is identified on transesophageal echocardiogram (TEE), and anticoagulation should be initiated and continued for 3–4 weeks before repeating the TEE.

In view of symptoms, morbidity, and prolonged length of ICU and total hospital stay associated with postoperative AF, prophylaxis may be reasonable in high-risk patients. For patients undergoing CABG surgery with or without valve replacement who are at high risk of AF, preoperative administration of β-blockers and/or amiodarone is reasonable. β-Blockers have been shown to significantly reduce the incidence of post-CABG AF; in a Cochrane systematic review, the odds ratio (95% confidence interval) for post-CABG AF associated with β-blockers was 0.35 (0.26–0.49). β-Blockers should not be discontinued before CABG surgery because preoperative β-blocker discontinuation increases the risk of postoperative AF. Oral amiodarone has also been shown to reduce the incidence of post-CABG AF and is recommended in patients at high risk of AF. Other drugs that may be considered for prophylaxis of post-CABG AF in patients at high risk include sotalol and colchicine. Drugs for prevention of post-CABG AF are presented in Table 35.4.

Pharmacologic prophylaxis of AF after noncardiac thoracic surgery is also recommended for intermediate- or high-risk patients. As with post-CABG AF, patients taking β-blockers before noncardiac thoracic
surgery should continue to take them postoperatively. Intravenous diltiazem has been shown to reduce the incidence of AF after noncardiac thoracic surgery. Amiodarone reduces the incidence of AF after pulmonary resection as well as after esophagectomy. Atorvastatin has been shown to reduce the incidence of AF after noncardiac thoracic surgery, as has intravenous magnesium. Drugs for prevention of AF after noncardiac thoracic surgery are presented in Table 35.5.

### VENTRICULAR ARRHYTHMIAS

#### Ventricular Tachycardia

**Features**

In this section, VT with a pulse will be discussed. Pulseless VT will be discussed in the chapter titled Management of Cardiac Arrest. For this chapter, VT refers to monomorphic VT, a tachyarrhythmia of ventricular origin for which the QRS complexes appear the same (i.e., have a single consistent morphology) (Figure 35.14).

Ventricular tachycardia may be nonsustained or sustained. Nonsustained VT is defined as three or more consecutive complexes in duration, at a rate of greater than 100 beats/minute, and which terminates spontaneously in less than 30 seconds. Sustained VT also occurs at a rate greater than 100 beats/minute, but it is greater than 30 seconds in duration or requires termination because of hemodynamic compromise in less than 30 seconds.

**Epidemiology**

The incidence of VT is variable and dependent on the etiology and underlying comorbidities. Around 2%–4% of patients having an acute MI develop sustained VT. Most of these patients experience VT within 48 hours of the MI, whereas a small proportion may develop VT later than 48 hours. Nonsustained VT occurs in 20%–80% of patients
The overall incidence or prevalence of VT in critically ill patients in ICUs has not been studied widely. In an epidemiologic study conducted in a 10-bed ICU in a university hospital in South America from August 1971 to April 1983, 502 of 2,820 patients (17.8%) developed “rapid ventricular arrhythmia.” Reinelt et al.\(^5\) reported that VT occurred in 54 of 756 patients (7.1%) in a medical-cardiology ICU at a university hospital during an almost 3-year period. A total of 135 episodes of VT (49% of all episodes of tachycardias) occurred in these 54 patients.

**Pathophysiology**
Ventricular tachycardia is usually triggered by a ventricular premature depolarization and is sustained by ventricular reentry.

**Etiologies**
In about 80% of cases, VT occurs in the setting of structural heart disease, primarily coronary heart disease and/or left ventricular dysfunction/cardiomyopathy.\(^2,85\) In the absence of structural heart disease, right ventricular outflow tract VT is the most common type.\(^89\) Other etiologies of VT include electrolyte abnormalities such as hypokalemia, hypoxia, and, rarely, drugs.\(^90\) Flecainide and propafenone can induce an incessant VT characterized by wide QRS complexes having a sinusoidal appearance.\(^91,92\) Flecainide was associated with increased mortality, because of presumed ventricular proarrhythmia, in patients after MI in the CAST study (Cardiac Arrhythmia Suppression Trial).\(^93\) In this study and its follow-up,\(^94\) the Vaughan-Williams class IC drugs encainide and moricizine were also associated with increased mortality caused by presumed ventricular proarrhythmia; therefore, flecainide and, by extension, propafenone are contraindicated in patients with any history of coronary heart disease. Ibutilide has been associated with episodes of nonsustained VT in about 5% of patients.\(^95\)
**Figure 35.12** Treatment algorithm for acute ventricular rate control in critically ill patients with hemodynamically stable AF. 

- **Risk Factors**

  Independent predictors of sustained VT after an acute MI include lower baseline systolic blood pressure, in-hospital use of intravenous lidocaine for post-MI VT prophylaxis, higher Killip class, faster heart rate, and advanced age. Female sex and β-blocker use within 2
weeks prior may be protective.\textsuperscript{86}

</tr>
</tbody>
</table>

\textsuperscript{a}Contraindicated in patients with WPW or other preexcitation syndromes.

\textsuperscript{b}Avoid in patients with QTc interval $> 440$ ms ($> 500$ ms in patients with ventricular conduction abnormalities).

\textsuperscript{c}Flecainide and propafenone are not available intravenously in the United States.

\textsuperscript{d}$\beta$-Blocker, diltiazem, or verapamil should be administered $\geq 30$ min before administration
Morbidity and Mortality
Post-MI VT portends a negative prognosis. In patients who experience VT after an acute MI who do not have HF or cardiogenic shock, the hazard ratio for 30-day mortality is 12.9 (7.8–21.3) and, for 1-year mortality, 2.5 (1.7–3.6). Ventricular tachyarrhythmias in critically ill patients are associated with an increased risk of mortality (relative risk 1.47 [1.29–1.67]).

Treatment
Ventricular tachycardia that is hemodynamically unstable should be treated with synchronized DCC. If time permits, the patient should be sedated for cardioversion. The initial recommended DCC dose is 100 J monophasic or biphasic waveform.

Drugs for treatment of hemodynamically stable VT are presented in Table 35.6. Drugs for VT termination include procainamide, amiodarone, sotalol, and lidocaine, all administered intravenously. In a randomized study, intravenous procainamide was significantly more effective at terminating spontaneous sustained monomorphic VT than lidocaine (12 of 15 patients [80%] vs. 3 of 14 patients [21%] with VT successfully terminated, p<0.01). Procainamide terminated 38 of 48 VT episodes (79%) compared with 6 of 31 VT episodes (19%) terminated with lidocaine. Intravenous amiodarone was shown to be effective for management of life-threatening ventricular arrhythmias in a double-blind dose-ranging study. Intravenous amiodarone was also found to be more effective than lidocaine for termination of incessant, shock-resistant VT (VT terminated in 78% of amiodarone-treated patients vs. 27% of lidocaine-treated patients, p<0.05). In addition, intravenous amiodarone has been shown to be effective for terminating sustained hypotensive VT refractory to therapy with procainamide, lidocaine, and bretylium. Evidence supports the efficacy of
intravenous sotalol for termination of hemodynamically stable monomorphic VT. Like procainamide and amiodarone, intravenous sotalol was found to be more effective than lidocaine for termination of spontaneous sustained VT in a randomized, double-blind study; VT termination rates in the sotalol and lidocaine groups were 69% and 18%, respectively (p=0.003). Because of the superior efficacy of procainamide, amiodarone, and sotalol, lidocaine should be considered a second-line therapy for termination of monomorphic VT. Intravenous procainamide and sotalol should be avoided in patients with HFrEF because of negative inotropic activity and an increased risk of TdP. A treatment algorithm for termination of ventricular tachycardia is presented in Figure 35.15. For patients who do not respond to maximally tolerated doses of drugs recommended in Figure 35.15, elective DCC may be necessary.

### Torsades de Pointes

#### Features

Torsades de pointes is a polymorphic VT associated with prolongation of the QT interval.\textsuperscript{102} The term torsades de pointes means “twisting of the points” and was originally named because of the ECG appearance of the “points” of the QRS complex twisting around the isoelectric baseline (Figure 35.16).\textsuperscript{103} Torsades de pointes is also characterized on ECG by a short-long-short RR interval pattern immediately preceding the onset of the arrhythmia.\textsuperscript{102} Heart rates during TdP range from 160 to 240 beats/minute.\textsuperscript{102} Although TdP often terminates spontaneously, it can degenerate into ventricular fibrillation and cause sudden cardiac death. QT interval prolongation and TdP may be congenital (congenital long QT syndrome [LQTS]) or acquired. Acquired QT interval prolongation and TdP is usually caused by drugs.\textsuperscript{90}

#### Epidemiology
Thirteen forms of the congenital LQTS have been identified. Overall, congenital LQTS occurs in about 1 in 2,000 live births. The incidence of TdP in patients with congenital LQTS is variable, about 14%–21% among patients younger than 12 years, 25% among patients 12–18 years of age, and 16%–39% among patients 18–40 years of age.

The overall incidence of drug-induced TdP in the general population is unknown. A population-based study in Sweden found an annualized incidence of TdP of 4 per 100,000. Extrapolation of that incidence to the population of the U.S. suggests that around 12,000–13,000 cases of drug-induced TdP may occur annually. However, a more recent study conducted in Berlin estimated the annual incidence of drug-induced LQTS/TdP in that city to be 2.5 per million in men and 4 per million in women. Extrapolation of those estimates to the U.S. population suggests a lower incidence of drug-induced LQTS/TdP, about 400 cases annually in men and 640 cases per women, for an annual number of just more than 1,000 cases. The incidence of drug-induced TdP in the U.S. requires further study. The risk of TdP associated with individual QT interval–prolonging drugs is 2%–12%.

QT interval prolongation is prevalent in critically ill patients. In a study conducted during a 1-year period in 1,159 consecutive patients admitted to two cardiac ICUs at a large academic medical center, Bazett’s corrected QT (QTc) interval prolongation was present in 28% of patients on admission, and 18% had a QTc interval greater than 500 milliseconds. Of these, 35% and 42%, respectively, were subsequently prescribed QT interval–prolonging drugs, despite being admitted with QTc interval prolongation. Pickham et al. reported that 24% of patients in adult ICU and progressive care units developed QTc interval prolongation. In a prospective cohort study of patients admitted to a mixed medical-surgical ICU, 52% had a QTc interval greater than 500 milliseconds during the ICU stay. The prevalence of QTc interval prolongation in critically ill patients is high because of a preponderance of risk factors, including comorbid conditions and frequent use of QT interval–prolonging medications.
The incidence of TdP in critically ill patients in ICUs has not been widely studied. Pickham et al. reported one case of TdP among 154 patients (0.6%) in adult ICUs and progressive care units during a 2-month period. This represented 1 of 16 cardiac arrests (6%) in these units during this time.

### Pathophysiology
Torsades de pointes occurs as a result of prolongation of ventricular repolarization and increased heterogeneity (dispersion) of ventricular repolarization. Drugs that induce TdP usually inhibit the rapid component of the delayed rectifier potassium current (I_{Kr}), resulting in prolonged ventricular repolarization and corresponding prolongation of the QTc interval. Torsades de pointes is likely triggered by early...
afterdepolarizations, the propensity for which is increased in the setting of prolonged ventricular repolarization. After triggered initiation, TdP is propagated by reentry.

**Etiologies**

As described, TdP may be congenital or acquired. Congenital LQTS leading to TdP is caused by mutations in up to 13 different genes, but more than 92% of cases are accounted for by mutations in KCNQ1, KCNH2, and SCNA5, which encode the slow component of the delayed rectifier potassium channel ($I_{Ks}$), $I_{Kr}$, and sodium channels, respectively. Acquired TdP is most commonly caused by drugs. Medications that may cause TdP include those from a variety of drug classes, including antiarrhythmic agents, antibiotics and other anti-infectives, antipsychotics, anti-depressants, and many others. A good resource for up-to-date lists of drugs that may prolong the QT interval and cause TdP is maintained on the website crediblemeds.org, which is maintained by AZCERT (Arizona Center for Education and Research on Therapeutics). Drugs that may cause TdP are listed in Table 35.7. Many of these drugs are used in the ICU, including antibiotics, antiarrhythmics, antiemetics, and others. In particular, intravenous haloperidol has commonly been used in ICUs for delusional agitation. Intravenous haloperidol has been associated with a high incidence of TdP in critically ill patients in some series, particularly in association with higher doses. Because of a lack of evidence of efficacy and the risk of QTc interval prolongation and TdP associated with intravenous haloperidol, the drug is no longer recommended for management of delirium in adult patients in the ICU.

Risk Factors

Risk factors for drug-induced TdP have been widely described. Drug-induced TdP is substantially dependent on risk factors and is a particularly rare occurrence in the absence of risk factors. In an analysis of 144 published articles describing 249 patients who experienced TdP induced by noncardiac drugs, almost 100% of the patients had at least one risk factor, and 71% of the patients had two or more risk factors.116

Risk factors for drug-induced TdP are listed in Box 35.2. The risk of TdP increases markedly when the QTc interval is prolonged to beyond 500 milliseconds.117 More than 90% of TdP cases occur when the QTc
interval is greater than 500 milliseconds, and TdP rarely occurs when the QTc interval is less than 500 milliseconds. The risk of TdP also may be increased when the QTc interval is prolonged greater than 60 milliseconds from pretreatment value. Women are at a higher risk of TdP than men, possibly as a result of proarrhythmic effects of estradiol in women or protective effects of testosterone in men. Hypokalemia, hypomagnesemia, and hypocalcemia increase the risk of TdP; hypokalemia was present in 28% of TdP associated with noncardiac drugs. Low extracellular potassium concentrations enhance drug-induced $I_{Kr}$ inhibition. Older age is a risk factor for TdP for reasons that are uncertain, but this could be related to declining serum testosterone concentrations in men and low serum progesterone concentrations in postmenopausal women. Heart failure with reduced ejection fraction is a prominent risk factor for drug-induced TdP; the incidence of TdP associated with drugs such as ibutilide and dofetilide is 2–3 times higher in patients with HFrEF than in patients with normal left ventricular function.

Figure 35.16  Torsades de pointes.

Some patients who develop drug-induced TdP may have an underlying genetic predisposition. Polymorphisms of genes associated with the congenital LQTS may be present in 10%–15% of patients with drug-induced TdP.\textsuperscript{123}

Risk factors for QTc interval prolongation in critically ill patients have been identified and incorporated into a QTc interval prolongation risk score, in which 1, 2, or 3 points was assigned to each risk factor.\textsuperscript{124} Independent risk factors for QTc interval prolongation in critically ill patients were similar to those associated with TdP and included age 68 years or older (1 point), female sex (1 point), taking a loop diuretic (1 point), serum potassium of 3.5 mEq/L or less (2 points), admission QTc interval of 450 milliseconds or greater (2 points), acute MI (2 points), HFrEF (3 points), receiving one QTc interval–prolonging agent (3 points), and receiving two or more QTc interval–prolonging drugs (3 points). In addition, sepsis was an independent risk factor for QTc interval prolongation (3 points).\textsuperscript{124} A risk score in the intermediate (7–10) or high (11 or more) range predicted critically ill patients at highest risk of developing QTc interval prolongation.\textsuperscript{124}

Morbidity and Mortality
Drug-induced TdP occurring in the ICU may be associated with prolonged duration of hospital stay. Torsades de pointes may remain hemodynamically stable, or it may be hemodynamically unstable and rapidly degenerate into ventricular fibrillation and cause cardiac arrest/sudden cardiac death.

Prevention and Treatment
In critically ill patients receiving drugs that may cause TdP, clinicians must be attentive to methods of reducing the risk of TdP. QTc interval–prolonging drugs should be avoided, whenever possible, in patients with a pretreatment QTc interval greater than 450 milliseconds. If a patient receiving a QTc interval–prolonging drug has a QTc interval increase of 60 milliseconds or greater from pretreatment value, the dose should be reduced or the drug discontinued whenever possible. Drugs with the potential to cause TdP should be discontinued if the QTc interval is prolonged to greater than 500 milliseconds. Serum potassium, magnesium, and calcium concentrations should be maintained within the normal range. When possible, avoid use of drugs with the potential to cause TdP in patients with HFrEF, particularly if the left ventricular ejection fraction is less than 20%. Doses of renally eliminated QTc interval–prolonging drugs should be adjusted in patients with acute kidney injury or chronic kidney disease. When possible, avoid using combinations of drugs that prolong the QTc interval. Avoid concomitant use of cytochrome P450 (CYP) system inhibitors and QTc interval–prolonging drugs that are CYP substrates. Avoid administering drugs with the potential to cause TdP in patients with a history of drug-induced TdP and in those with a diagnosis of the congenital LQTS. Critically ill patients receiving therapy with a QTc interval–prolonging drug should be maintained on continuous telemetry monitoring, and the QTc interval should be documented every 8–12 hours.

Box 35.2. Risk Factors for Drug-Induced TdP
- QTc interval > 500 ms
- Increase in QTc interval ≥ 60 ms from pretreatment value
- Female sex

- Hypokalemia
- Hypomagnesemia
- Hypocalcemia
- Treatment with diuretics
- Bradycardia
- Sequential bilateral bundle branch block
- Elevation in serum concentration of QTc interval–prolonging drug because of drug interaction or inadequate dose adjustment for kidney disease
- Rapid intravenous injection of QTc interval–prolonging drug
- Possible genetic predisposition
- History of drug-induced TdP

HFrEF = heart failure with reduced ejection fraction; TdP = torsades de pointes.

A treatment algorithm for management of TdP in critically ill patients is presented in Figure 35.17. Patients with TdP that is hemodynamically unstable should undergo asynchronous defibrillation, rather than synchronized cardioversion, because synchronization of shocks in polymorphic arrhythmias is often impossible. In patients with TdP that is hemodynamically stable, intravenous magnesium is recommended, primarily on the basis of two observational
In patients who do not respond to intravenous magnesium, isoproterenol or overdrive pacing may be used if patients have TdP that is associated with bradycardia or that appears to be precipitated by pauses in rhythm. Elective defibrillation may be used in refractory cases that are hemodynamically stable. Refractory TdP associated with sotalol has been successfully managed using hemodialysis or peritoneal dialysis.

**Figure 35.17** Treatment algorithm for critically ill patients with TdP.

**INTRODUCTION**

Mechanical circulatory support (MCS) is a broad-reaching description of the advanced technology and capability available today to support patients with acute or chronic hemodynamic compromise when conventional therapies have failed or are unsustainable. As MCS has evolved, so has its implementation into clinical practice. As will be discussed later in this chapter, the options for MCS largely depend on the primary organ system needing support—cardiovascular/cardiopulmonary versus pulmonary only. Long-term cardiovascular support with durable implantable ventricular assist devices (VADs) and the total artificial heart provide a management option in end-stage heart failure beyond the traditional construct of palliative care versus transplantation. However, short-term cardiac support allows options to provide acute cardiovascular MCS for temporary support with intra-aortic balloon pumps (IABPs), paracorporeal/extracorporeal VADs, or extracorporeal life support (ECLS)/extracorporeal cardiopulmonary resuscitation (ECPR) by venoarterial (VA) extracorporeal membrane oxygenation (ECMO).\(^1\)\(^-\)\(^5\) However, ECLS by venovenous (VV) ECMO has grown significantly as a promising modality of therapy for patients with severe acute pulmonary failure.\(^3\)\(^,\)\(^6\)

Early descriptions of MCS were documented in the early 19th century and further described in the 1930s.\(^7\) However, these therapies were first applied to human subjects in 1953 by J. Gibbon Jr using a heart-lung machine for atrial septal defect repair and in 1954 by C.
Walton Lillehei, M.D., to successfully perform cardiac surgery using controlled cross-circulation and a bubble oxygenator.\textsuperscript{8,9} Many notable events have been pioneered to bring us to the advances in MCS we see today (Table 36.1).

Although thoracic organ transplantation is commonly considered the gold standard treatment for end-stage heart or lung disease, growing comorbidities, psychosocial concerns, and lack of donor organ availability have driven the advancement of MCS, particularly for cardiovascular support. As MCS has advanced, implantable VADs have evolved from large pulsatile devices to smaller, more durable continuous flow devices. Other advances have allowed exploration into further application of MCS for other populations. In the severely critically ill patient with cardiac or cardiopulmonary compromise, the growing application of ECLS has shown that MCS may have a role in hemodynamic support beyond the operating room or in end-stage heart failure. Extracorporeal membrane oxygenation and ECLS are forms of mechanical respiratory and circulatory support that have considerably evolved during the past decade.\textsuperscript{10} With new developments in this technology, use in adults has been growing rapidly, a trend that was initially seen after the 2009 influenza A (H1N1) pandemic.\textsuperscript{11,12} The growing use of MCS and increasing complexity of available devices, in addition to the complicated pathophysiology and pharmacotherapeutic support requirements of these patients, deliver an undeniable need for the critical care clinician to understand the principles and ramifications of MCS.

INDICATIONS AND TYPES OF MCS

The type of MCS, as well as the intent and potential duration, depends on several factors, including patient acuity, comorbidities, and prognosis. The progression and options for support can be dynamic, given a patient’s clinical progress and etiology of hemodynamic compromise. As a general construct, the options for support can be divided according to the primary organ dysfunction (respiratory vs. cardiac) and can further be divided into temporary versus long-term MCS (Table 36.2). For some cardiac indications, a patient may be optimized and go directly to long-term MCS. All forms of MCS are considered a “bridge” or intervention to a progressive improvement in a patient’s clinical status—be it a “bridge” to recovery from the acute pulmonary or cardiac disease; a “bridge” from a temporary to a durable MCS device; or a “bridge” from chronic MCS to transplantation or palliative care. Particularly in relation to long-term MCS, the intent should be declared before the time of implantation with the understanding that during long-term support, clinical factors (new improvement or deterioration) may influence change in the intent of support (Figure 36.1). For long-term MCS, the intent of the “bridge” has been defined by INTERMACS (Interagency Registry for Mechanically Assisted Circulatory Support) as described in Table 36.3.

Resource use and the fundamental oath of primum non nocere (first,
do no harm) are notwithstanding when it comes to patient selection. As such, MCS strategies must consider contraindications that account for complications during MCS and therapies required during support, in addition to the reversibility of the patient’s disease state and likely prognosis when considering comorbidities (Table 36.4 and Table 36.5).

GENERAL DEVICE OVERVIEW AND SETTINGS

The MCS devices available for clinical use can vary among institutions; however, for some devices, availability can also differ according to enrollment and participation criteria for clinical trials as well as indication approval/availability by country. In general, each device is connected to a controller that mediates the speed or vacuum/rate of the respective pump, and the speed most directly dictates power consumption of the respective pump (other factors may also play a role in power consumption). Aside from IABPs, a list of MCS devices can be found in Table 36.6. Although somewhat proprietary to each device, almost all MCS devices require some level of anticoagulation, which will be discussed later in the chapter.

IABP Counterpulsation

An IABP is generally placed by femoral arterial catheter (in some scenarios, it can also be placed by left brachial, axillary, or subclavian arteries) and advanced into the descending thoracic aorta. The IABP is an intervention that can provide selective systolic afterload reduction while enabling diastolic augmentation of blood pressures, all contributing to sustaining an increased mean arterial pressure. Intra-aortic balloon pump deflation provides systolic afterload reduction to ease cardiac work (does not directly increase cardiac output). Subsequently, IABP inflation enables diastolic augmentation of systemic mean arterial blood pressures through displacement of blood to increase mean arterial perfusion pressure. The timing of IABP inflation and deflation can be set to trigger from electrocardiogram, pacemaker, or arterial line pressures or can be manually set. Patients with aortic valve regurgitation/insufficiency may not benefit from this means of
afterload reduction because of worsening regurgitation during diastole. Patients with tachyarrhythmias and/or irregular heart rates may have less-than-optimal IABP synchronization. The level of support from an IABP coincides with the timing of inflation/deflation per related heartbeat. For example, 1:1 is one inflation/deflation per every heartbeat (maximal support), and 1:4 is one inflation/deflation for every fourth heartbeat (less support). Blood flow stagnation associated with decreasing of IABP support increases the thrombotic risk and may warrant anticoagulation. Immobility is a predominant limitation to this form of MCS that is particularly seen when the IABP is placed femorally.

**Percutaneous VADs**

Currently, a handful of MCS devices can be used for temporary support. In the United States, such devices include the TandemHeart pVAD (Cardiac Assist, Pittsburgh, PA) and the Impella (Abiomed, Danvers, MA). Future developments may include newer or modified percutaneous devices to provide left ventricular support that is more robust, but these are also being developed to provide less invasive right ventricular support. These devices are currently used
predominantly in cardiogenic shock or as temporary support during high-risk interventional or electrophysiological cardiac procedures. The TandemHeart pVAD device (Cardiac Assist, Pittsburgh, PA) can be used as an MCS device capable of providing up to 8 L/minute of support by centrifugal pump (continuous non-pulsatile blood flow). Depending on the manner of configuration, it is capable of providing left ventricular support by atrial transseptal puncture cannulation, or using an alternative cannula (Protek Duo), it may also be set up to provide right ventricular support or enable VV-ECLS. Another device, the Impella (Abiomed), comes in differing platforms enabling 2.5, 3.5, or 5.0 L/minute of non-pulsatile blood flow support to the left ventricle. These devices are placed into the aorta across the aortic valve percutaneously for the 2.5- or 3.5-L/minute platforms or by surgical placement if using the 5.0-L/minute platform. As it resides in the left ventricular cavity, blood is suctioned into the inflow port and through the outflow port in the ascending aorta. The anticoagulation regimen for this device is a common topic of debate and medication safety discussion because it requires a heparinized dextrose purge solution (ranging from D$_5$W to D$_{50}$W) to lubricate and cool the rotary motor and minimize blood-motor interface. Management can be complicated by migration and malposition of the catheter/cannula within the left ventricle, leading to arrhythmias and hemolysis. Specific contraindications to this device include mechanical aortic valve, moderate to severe aortic stenosis, moderate to severe aortic insufficiency, and severe peripheral vascular disease. More recently the Impella RP (Abiomed) was introduced to the market as a temporary MCS device that can provide support to those with acute right ventricular dysfunction/failure. Configured slightly different than the other Impella devices, the Impella RP is placed in the femoral vein and advanced to reside with the inflow area within the inferior vena cava and outflow within the pulmonary artery. A pulmonary artery catheter is commonly used concurrently, however, cardiac outputs are favored to be calculated by Fick method rather than thermodilution because of the heat generated by the pump and subsequent interference. A heparin purge solution is still required with this device.

Bridge to candidacy OR bridge to recovery

Designation used to describe the approach to temporary MCS when short-term LVADs are used to support a patient until a long-term prognosis can be determined, which may include explantation with recovery, implantation of long-term durable LVAD support, heart transplantation, or palliative care.

BTT = bridge to transplantation; LVAD = left ventricular assist device; MCS = mechanical circulatory support

Extracorporeal or Paracorporeal VADs
Various extracorporeal VADs are available, although some common examples include the Thoratec CentriMag Blood Pump (Thoratec Corporation, Pleasanton, CA), BVS 5000 Ventricular Support System (Abiomed), and AB5000 Circulatory Support System (Abiomed). The CentriMag Blood Pump provides up to 9 L/minute of continuous non-pulsatile blood flow by a magnetically levitated impeller. Although commonly used for a longer duration, this device is approved by the U.S. Food and Drug Administration (FDA) for up to 6 hours of MCS as a bridge to decision for other advanced therapies, but it is also approved by the FDA for use as a right VAD for up to 30 days for patients in cardiogenic shock caused by acute right ventricular failure.27,28 The BVS 5000 (Abiomed) can be used for temporary unilateral (left or right) or biventricular support. This device is a more simplistic VAD with two sac-like chambers that fill semi-passively by gravitational force and that are subsequently emptied by an air-driven pump to deliver up to 6 L/minute of pulsatile blood flow by displacement. The filling chamber should be watched closely for signs of thrombus development.29 The AB5000 Circulatory Support System (Abiomed) can also be configured for use as temporary unilateral (left or right) or biventricular support. This device rests in a paracorporeal manner on the chest of the patient and, through vacuum assistance, can provide up to 6 L/minute of pulsatile blood flow.30

Durable Implantable VADs and Total Artificial Hearts
Ongoing developments have continued to enable prolonged MCS to patients. Early durable VADs, such as the Heart-Mate XVE, were quite large with large-bore drivelines and mediated pulsatile flow by an electrically controlled pusher plate that displaced blood and required minimal anticoagulation. However, the life span of this device was limited by the wear and tear on the metal bearings in the motor as well as the potential acquired dysfunction of the integrated porcine valves within the inflow and outflow cannula/conduits. This device has since been replaced in therapy with newer continuous-flow, non-pulsatile VADs (either axial or centrifugal flow), which has facilitated much longer pump life. Although requiring full anticoagulation, these newer devices such as the HeartMate II (Thoratec, Pleasanton, CA) and HeartWare HVAD (HeartWare, Framingham, MA), have provided acceptable risk profiles for thrombosis and bleeding in clinical trials. Simplistically, these devices are implanted by placing an inflow cannula/conduit into the apex of the left ventricle, which pulls blood through the pump to exit...
through the outflow graft that is attached to the ascending aorta. Although these devices provide selective support of the left ventricle, the care management must also facilitate appropriate medical management of right ventricular support to enable successful patient treatment. For implantable devices, the connection to the power source and controller is enabled by a driveline that is usually tunneled through the abdomen to an exit site. In select patients, a total artificial heart may be considered, particularly in patients with biventricular heart failure who are listed for heart transplantation. The HeartMate II (Thoratec) can deliver up to 10 L/minute of blood flow by an axial rotor that spins at 8,000–15,000 rpm. The device controller provides alarms regarding flow disturbances, pump failure, low power, power or connection disruptions, and controller malfunction. The HeartWare HVAD (HeartWare) provides up to 10 L/minute by a centrifugal flow impeller spinning at 2,000–3,000 rpm.

**ECLS or ECMO**

Similar to cardiopulmonary bypass, ECLS/ECMO drains venous blood through large-bore cannulas, pumped through an oxygenator (usually by means of a centrifugal, non-pulsatile pump), where it is oxygenated and cleared of carbon dioxide and then actively pumped back into the
body. The modality of support depends on the means of vascular cannulation. Venovenous cannulation removes deoxygenated venous blood from the vena cava and returns blood near the right atrium after circulating through the oxygenator and circuit; it requires the heart to circulate blood to maintain end-organ perfusion. Venoarterial cannulation is more complex. With peripheral cannulation, the venous inflow cannula removes blood from the vena cava by the femoral vein and delivers oxygenated blood by femoral or axillary artery outflow cannula to the descending aorta, resulting in retrograde flow to the ascending aorta. Central cannulation, commonly seen post-cardiotomy, removes blood from the right atrium and delivers oxygenated blood into the ascending aorta immediately distal to the coronary sinus. Femoral cannulation of VA-ECMO can increase the risk of lower limb ischemia obstruction of distal blood flow. This may be avoided by placing a distal perfusion catheter to either the femoral artery or a distal site such as the posterior tibial or dorsalis pedis arteries. Because of the low-flow state within the heart, VA-ECMO can be associated with a risk of intracardiac and/or aortic root thrombus.

Considerations of which populations may be considered for VV-ECMO versus VA-ECMO are outlined in Table 36.2. Beyond anticoagulation considerations, ECMO/ECLS presents considerably more pharmacologic challenges, as will be outlined in the following section. Extracorporeal membrane oxygenation/ECLS has evolved significantly, with almost 250 centers registered with the Extracorporeal Life Support Organization, allowing for variation in circuit setup and management. Although the components required are fundamentally the same (pump, oxygenator, circuit tubing, and cannula), variation in pharmacologic interactions has been described among different proprietary constituents of these ECMO/ECLS circuits.

PHARMACOLOGIC CHALLENGES WITH MCS

Drug-Circuit Interactions and Considerations—Overview
When administering a drug, there is a balance between the dose administered and the elicited response, with the goal of providing a therapeutic effect while minimizing toxicity. This relationship between the drug dose and response may be altered in critically ill patients as a result of pharmacokinetic and pharmacodynamic changes. The use of ECMO can lead to additional pharmacokinetic alterations. Providing optimal dosing regimens for patients receiving ECMO requires a working knowledge of pharmacokinetic and pharmacodynamic alterations propelled by drug, disease, and extracorporeal factors (Figure 36.2). Despite improvements in this technology and resurgence of its application for respiratory failure, there remains a paucity of evidence and understanding of pharmacotherapy in patients receiving MCS. Almost all of the data that have been published on changes in pharmacokinetics during MCS have been with ECMO, with few or no data published regarding pharmacokinetic changes in patients with heart failure having VADs.

The elimination of drugs from the body is highly dependent on clearance and volume of distribution. The liver and the kidneys serve as the two major organ systems responsible for drug elimination. Additional losses of drugs through the skin and gastrointestinal tract or biliary excretion can serve as minor pathways of drug elimination. Organ impairment or failure, altered plasma protein binding, increases in circulating volume, and perfusion abnormalities are often encountered in critically ill patients, resulting in changes in absorption, distribution, metabolism, and elimination of the drugs, creating challenges in drug dosing. In addition, patients receiving ECMO may have an array of pathophysiological changes, including acute kidney injury and decreased hepatic blood flow, leading to changes in drug clearance; however, these changes from ECMO may be difficult to ascertain in the already critically ill patient.
The complex interplay between physiochemical properties of the drug(s), disease-specific alterations in pharmacokinetics in the critically ill, and extracorporeal factors.

Changes in volume of distribution owing to ECMO may be caused by hemodilution, sequestration of drugs as a result of circuit-related factors, decreased circulating albumin, or alterations in protein binding from pH aberrations. Priming solutions (plasma, saline, or albumin) that are used on initiation of ECMO increase the patient’s circulating volume and may lead to pharmacologic alterations with hydrophilic drugs, resulting in potentially decreased plasma concentrations. In addition, the dilution of plasma proteins, notably albumin, may affect highly protein bound drugs, leading to potential toxicities as a result of an increased proportion of unbound fraction of the drug.

Data concerning drug sequestration within the ECMO circuit are limited. The membrane oxygenator and polyvinyl chloride (PVC) tubing are two circuit components that provide a large surface area for drug sequestration, leading to potential drug loss over time. Some studies have shown that both the PVC tubing and the membrane oxygenators absorb drugs to a similar extent, whereas others have shown significant differences. Results from a simulated circuit showed an average of 80% loss of fentanyl in the circuit without
oxygenators at 120 minutes, with only an additional 5% loss when a Quadrox D oxygenator was added.\textsuperscript{39} Up to 40% of morphine was lost in all circuits, and no differences were noted in those with and without oxygenators.\textsuperscript{39} A saturation point may exist, leading to liberation of sequestered drug back into the circulation; however, this concept has not been studied.

Understanding the physicochemical properties of drugs can assist in determining the relationship between the dose administered and the anticipated concentration achieved in the blood.\textsuperscript{41} The octanol-water partition coefficient is a common way to report a drug’s measure of lipophilicity.\textsuperscript{43} Log $P$, the logarithm of the ratio of the concentrations of the unionized solute in the solvents, may be used to understand the behavior of drug molecules.\textsuperscript{43} Therefore, drugs with high log $P$ values (around 2.0) will have a propensity to be very soluble in organic materials such as the plastic tubing used in the ECMO circuit.\textsuperscript{44} However, to date, there has been no characterization of the drug-circuit interaction beyond 24 hours, and as such, little speculation can be made regarding the adsorptive capacity of the circuit over longer periods of ECMO support.

Overall, data are sparse relating to drug dosing in adult patients receiving ECMO. However, extrapolations from ex vivo studies may be useful to anticipate alterations in the pharmacokinetics of a drug that may occur during ECMO. In addition, some generalizations can be made with hydrophilic versus lipophilic drugs. Lipophilic drugs tend to be more affected by the ECMO circuitry and may require higher-than-expected dosing regimens to achieve the same therapeutic effect without ECMO (Figure 36.3).
Drug-Circuit Interactions and Considerations—Analgesia and Sedation

The provision of analgesia and sedation is common practice for mechanically ventilated patients in the ICU to provide comfort and maintain patient safety. Medication selection should be based on the patient’s needs, with titration to a predetermined goal in accordance with recently published guidelines. The use of analgesia and sedation during ECMO contributes to the reduction in oxygen consumption, facilitates patient-ventilator synchrony, diminishes patient stress and discomfort, and prevents patient-initiated device dislodgement or removal.

Results from several investigations using ex vivo models have shown a loss of analgesics and sedatives within the ECMO circuit. These studies using neonatal ECMO circuits composed of PVC tubing and silicone rubber membrane oxygenators established an early loss of...
commonly used sedatives. One investigation observed up to a 68% loss of midazolam and a 98% loss of propofol within 40–120 minutes. Steady morphine concentrations have been observed over time, with only about 20% drug loss over 6–24 hours. However, in contrast, significant reductions in fentanyl concentrations have been observed within 3 hours. Reductions of up to 30% from the original concentration of lorazepam have also been detected. An adult ECMO in vitro circuit using PVC tubing with a hollow polymethylpentene fiber membrane oxygenator showed up to a 93% decrease in dexmedetomidine concentrations at 24 hours. A more recent study used ex vivo ECMO circuits to measure concentrations of morphine, fentanyl, and midazolam throughout a 24-hour period. At 24 hours, average drug recovery relative to baseline from both the circuits and the controls was lower with the lipophilic drugs, including fentanyl 3%, midazolam 13%, and morphine 103%. Of interest, in the first hour of the ECMO run, up to 70% and 50% of fentanyl and midazolam, respectively, were lost in the circuit, and fentanyl was undetectable at 24 hours. Because of the lack of sequestration of morphine in the ECMO circuit, it would seem to be a preferred agent for prolonged periods of ECMO; however, the risks of accumulation, especially in patients with renal injury; the profound hypotensive effects; and the deliriogenic effects make morphine an unattractive agent for prolonged sedation.

Adult patients receiving ECMO for respiratory failure appear to have increased requirements of analgesia and sedation over time. A small, single-center, retrospective study showed an increase in the daily dose of midazolam on average by 18 mg (p=0.001) and morphine on average by 29 mg (p=0.02). Patients receiving VV-ECMO had a significantly higher daily midazolam dose requirement than did patients receiving VA-ECMO (p=0.005). Despite these studies showing an increased need for analgesics and sedatives during ECMO, it remains unknown whether the increased requirements clinically observed are a result of circuit-related factors alone or whether other factors such as tolerance, age, or organ function are contributors. To date, data are sparse to guide the
appropriate dosing of analgesics and sedatives in adult patients receiving ECMO with newer technology. Furthermore, there is a lack of outcomes data associated with these observational experiences. One approach to achieving adequate deep sedation in patients receiving ECMO would be to start with continuous infusions of both an analgesic and a sedative, anticipating requirements that exceed standard doses. In addition, establishing daily sedative goals with the potential for sedative interruption, anticipating significant dose reductions at ECMO discontinuation, and monitoring for signs of withdrawal and delirium should be considered.

Drug-Circuit Interactions and Considerations—Anti-infective Agents
Infections are commonly encountered in critically ill patients. Source control in addition to timely and appropriate antimicrobials remains the cornerstone to the success of the treatment for a critically ill patient. Most antimicrobial dosing regimens are established in healthy adults with normal physiology; however, significant changes in rate of clearance and volume of distribution may have profound effects on drug concentrations in the critically ill patient on ECMO. The changes in clearance and volume of distribution could result in substantial drug losses, leading to therapeutic failures, development of resistance, and worse outcomes. Monitoring of drug concentrations is not possible with many anti-infective agents; therefore, clinicians must rely on knowledge of a drug’s physiochemical properties, pharmacokinetic characteristics, and published experience to guide appropriate dosing. Until recently, there has been very little in the literature on the effects of antimicrobial dosing in the critically ill adult patient receiving ECMO.

Vancomycin
Vancomycin pharmacokinetics has been described in adult patients receiving ECMO. Using a population pharmacokinetic model for vancomycin, a significant decrease in clearance and increases in volume of distribution were observed in a mixed population receiving
ECMO. A more recent study compared the pharmacokinetics of vancomycin in adult patients receiving continuous infusion vancomycin with and without the use of ECMO. All patients received a 35-mg/kg loading dose over 4 hours, followed by a continuous infusion aimed to target a serum concentration of 20–30 mg/L. Throughout the first 24 hours of the study, there were no differences in clearance or volume of distribution between the two groups. In addition, an ex vivo study showed very little loss of vancomycin using modern adult ECMO circuitry. Current dosing of vancomycin in critically ill adult patients receiving ECMO appears to be no different than critically ill patients not receiving ECMO; however, because therapeutic drug monitoring is widely available, concentrations should be routinely monitored to ensure adequate therapy.

**Aminoglycosides**

Aminoglycosides have concentration-dependent killing, often used in conjunction with other gram-negative antimicrobial agents to treat life-threatening infections in adult patients. As a class, these agents are hydrophilic, with a low molecular weight, low protein binding, and a small volume of distribution. The study of aminoglycoside pharmacokinetic alterations with ECMO is largely limited to the neonatal population. These studies have consistently observed a significant increase in volume of distribution and a decrease in clearance leading to an extension of the dosing interval in this population, despite the variability in trial design and methodology. No studies currently address the pharmacokinetic changes of aminoglycosides in the adult patient receiving ECMO; however, because of the highly hydrophilic nature of this class, no changes in clearance as a result of sequestration would be expected. Therapeutic drug monitoring is readily available for this class of anti-infectives, thereby ensuring effective concentrations to treat the infection while limiting nephrotoxicity.

**Penicillins/Extended-Spectrum**

**Penicillins/Cephalosporins/Carbapenems**
There is no adult literature on changes in pharmacokinetic parameters in adult patients receiving ECMO with the penicillin, extended-spectrum penicillin, or cephalosporin antimicrobial classes. These classes of anti-infectives are commonly used in the treatment of gram-negative infections in the critically ill patient population. They have time-dependent bactericidal effects and are therefore most effective when concentrations are maintained above the minimum inhibitory concentration for at least 40% of the dosing interval. Substantial increases in meropenem clearance were observed in two patients receiving ECMO for treatment of severe respiratory failure secondary to pneumonia. Only when the dose of meropenem was administered as a high-dose infusion (6.5 g every 24 hours) were optimal concentrations attained. Supporting this concept, a recent ex vivo ECMO study observed a 24-hour average drug recovery relative to baseline from the circuits and controls for meropenem to be 20% and 42%, respectively. Increases in volume of distribution and clearance of meropenem have been observed in the critically ill patient with sepsis not receiving ECMO, leading to suboptimal drug concentrations. Mechanical circulatory support can induce a systemic inflammatory-like response, independently from sepsis, augmenting clearance and volume of distribution. In addition, significant meropenem degradation has been observed at ambient temperatures (37°C); this may therefore lead to inaccurate conclusions of the effects of ECMO circuitry on increased clearance. Dosing regimens in the adult patients receiving one of these anti-infective classes should account for these significant changes in pharmacokinetics while the patients are receiving ECMO, resulting in higher doses with more frequent dosing intervals, extended infusions, or continuous infusions.

**Antifungals**
Few studies have been published on the pharmacokinetic changes of antifungal agents in adult patients receiving ECMO. Significant drug sequestration of voriconazole has been observed in an ex vivo model. The authors observed a 71% loss of voriconazole at 24 hours. One case report observed undetectable voriconazole serum concentrations
despite dose increases (8 mg/kg) in an adult patient receiving ECMO.\textsuperscript{61} However, in another case report, voriconazole concentrations were sustained with an increased dose.\textsuperscript{62} Given the relatively high lyophilic nature of voriconazole, it would not be surprising to have decreased plasma concentrations with recommended doses; however, there are no current recommendations on dosing regimens in critically ill patients receiving ECMO. Conflicting case reports have been published on caspofungin, observing either no effect on pharmacokinetic parameters or an increase in clearance.

**Others**
The results of a case series in adult patients receiving linezolid and ECMO showed alterations in linezolid pharmacokinetics.\textsuperscript{63} Two of the three patients had no changes in volume of distribution, with one patient with cystic fibrosis having a substantial decrease in volume of distribution, and all three patients had an increased clearance.\textsuperscript{63} The hydrophilic nature of this drug and the documented variability of linezolid serum concentrations in critically ill patients potentially caused by augmented renal clearance may influence these pharmacokinetic alterations to a greater extent than sequestration from the ECMO circuit.\textsuperscript{64} One case reports no pharmacokinetic changes in a patient receiving ECMO.\textsuperscript{65} Many tigecycline classes of anti-infectives are used in the critically ill patient receiving ECMO; however, no data have been published in adult patients thus far.

---

**COMPLICATIONS OF MCS**
Complications of MCS can be multifactorial, which, in some cases, may partly be a result of the comorbidities of the patient population. Nonetheless, there are commonalities largely related to neurologic events, bleeding, thrombosis, hemolysis, device malfunction, or infection (see Table 36.6).

---

**BLEEDING, THROMBOSIS, AND ANTICOAGULATION**
Fundamentally, successful MCS depends on the function of the MCS device and its impact on the intrinsic rheologic properties of blood and particularly its influence on key interactions in thrombosis and hemostasis. Many proprietary MCS devices (predominantly VADs) provide device-specific anticoagulation recommendations, although the translation of these recommendations into practice is sometimes limited by clinical processes, variance in coagulation assays, coagulation assay availability, and interpretation. Nonetheless, anticoagulation strategies for MCS are without robust data, but often, they are standardized within a given institution. For temporary MCS, the most widely used form of systemic anticoagulation is heparin, and in some centers, aspirin and other antiplatelet agents are also integrated (see Table 36.7 for examples). In addition, some centers have used alternative parenteral anticoagulation with direct thrombin inhibitors (e.g., bivalirudin or argatroban), even in the absence of active concerns for heparin-induced thrombocytopenia. For long-term MCS, recommendations are largely proprietary and device-specific, with the commonalities in the anti-thrombotic regimens being aspirin, warfarin with variable patient/institutional targets, and variable use of parenteral anticoagulation among institutions for perioperative anticoagulation bridging (see Table 36.7 for examples). Nonetheless, the safety and efficacy of apixaban, dabigatran, rivaroxaban, enoxaparin, or other anticoagulants in patients with MCS devices has not been established.

Coagulopathies that may occur because of MCS include fibrinolysis and acquired von Willebrand syndrome, thereby increasing bleeding risk. The development of acquired von Willebrand syndrome has been described in both ECLS and VAD populations. Procedural- and surgical-related bleeding commonly are sources of major bleeding; however, some of the most common other sources include significant epistaxis or gastrointestinal bleeding. In some scenarios, this may be isolated to the identified arteriovenous malformations or angiodysplasias that are thought to be related to decreases in pulse pressure concomitantly with increased continuous flow pressures within the capillary bed, leading to the exposure of existing arteriovenous malformations or the development of new ones.
In contrast, there remains potential increased thrombotic risk secondary to infection as well as hemolysis. Infection, particularly bacteremias, is sometimes a forgotten thrombotic risk factor not well characterized in MCS. The complex interaction of the inflammatory and coagulation cascades existing in sepsis can be further complicated in patients undergoing MCS. Because the circulatory dynamics are somewhat compensated for in MCS patients with sepsis, the first presenting symptom of sepsis is sometimes hemoglobinuria or hemolysis. Hemolysis or pump thrombosis can have varying presentations including pump-related alarms (often indicating low flow and/or power elevations), which may also coincide with hyperkalemia, new non-hemorrhagic anemia, or urine color changes (may appear as hematuria, but in severe cases, can be tea-colored, brown, or black). It is also important to recognize that hemolysis may occur because of several other factors within the MCS circuit (Figure 36.4). At a minimum, at least low levels of mechanical hemolysis can be expected with most forms of MCS. However, worsening hemolysis may potentiate further ramifications that commonly appreciated. Through hemolysis, hemoglobin is liberated from the red blood cells into circulation, together with other intracellular enzymes and electrolytes. Circulating plasma-free hemoglobin is usually scavenged by haptoglobin, thus limiting downstream effects. However, in severe hemolysis when haptoglobin cannot maintain this balance, plasma-free hemoglobin may facilitate a prothrombotic state. This state may be enabled through direct platelet activation by plasma-free hemoglobin as well as scavenging of endothelial derived nitric oxide that, under normal circumstances, minimizes thrombotic interactions of the endothelium and platelets. Further end-organ damage may be mediated by hemolysis such as acute kidney injury. Although more investigation is still needed on the optimal detection and management, current recommendations indicate further workup for hemolysis and device thrombosis if lactate dehydrogenase (LDH) is 2.5–3 times the upper limit of normal (normal range 140–280 IU/L) or if the plasma-free hemoglobin is greater than 40 mg/dL (normal 0–10 mg/dL).
Coagulation and Testing During MCS

Expected changes in the coagulation are expected during MCS, including activation and amplification of the coagulation cascade and activation of platelets—all largely because of continual interaction with an artificial surface. Differing attempts for advancement have been made to lessen this effect such as altering the surface of the device (as seen in the Heartmate XVE) or enhancing the bio-compatibility of the tubing by adding bonded surfaces to the inner lining.

Currently, the only available guidelines for MCS anticoagulation are the 2014 ELSO Anticoagulation Guidelines and the 2013 International Society of Heart and Lung Transplantation (ISHLT) Guidelines for Mechanical Circulatory Support, both of which provide general recommendations on the management according to the available evidence.\textsuperscript{2,83} In both acute and chronic management, monitoring coagulation parameters is imperative to navigating the delicate balance between bleeding and thrombotic complications. Nonetheless, the science surrounding the optimal management and monitoring of antithrombotics and hemostatics remains quite uncertain—as evidenced by considerable variability in practice and gaps in supporting evidence. Heparin therapy has been the mainstay for anticoagulation in the acute setting for many disease states, including those in the MCS population. One of the most common areas of clinical debate and uncertainty revolves around heparin therapy in MCS. The debate is at least 3-fold surrounding the monitoring assays (ACT [activated clotting time], activated partial thromboplastin time [aPTT], and anti-factor Xa [anti-Xa]); the definition of “therapeutic range,” particularly with aPTT and anti-Xa; and the role of antithrombin. Debate exists largely because of the lack of consistent evidence to guide therapy and the inability to directly translate the evidence into practice among institutions. The best example of this is the definition of a heparin therapeutic range. Years ago, Chiu and colleagues established heparin therapeutic ranges for aPTT monitoring in an animal model deriving a ratio-based goal of aPTT of 1.5–2.5 times the baseline aPTT.\textsuperscript{84} Some guidelines and institutions still apply this in practice, which results in common aPTT goals of 40–60 seconds or 60–80 seconds. However,
concerns about data with this ratio-based heparin therapeutic goal approach were published by Brill-Edwards and colleagues, where protamine titrations of heparinized samples had considerable sensitivity variation among aPTT reagents, thus refuting ratio-based aPTT goals for heparin monitoring. Today, many laboratories use a modified Brill-Edwards method with an anti-Xa correlation curve to derive an institution-specific aPTT therapeutic range for heparin monitoring. Fundamentally, this presents inherent limitations in translating heparin anticoagulation goals between institutions.

Table 36.7  Example of Initial Post-MCS Insertion Antithrombotic Regimen

Antithrombotic Regimen

\[\text{Antithrombotic Regimen}\]

\[\text{Example of Initial Post-MCS Insertion}\]
Monitoring and adjustments should be made at routine feasible time windows that adhere to both blood conservation considerations and safe, assertive antithrombotic management.

Recent interest in anti-Xa monitoring of heparin also stimulated similar interest within the MCS population, and so far, anti-Xa and aPTT monitoring have shown discordance. Anti-Xa activity may be a potential option, but they are not well validated in all populations, particularly the MCS population. As previously mentioned, all MCS
types induce at least minimal levels of mechanical hemolysis. Of note, the presence of hyperbilirubinemia or hemolysis has been shown to influence the chromogenic anti-Xa assay, potentially representing the activity as falsely low. Overall, anticoagulation management and monitoring during MCS remains a conundrum. The roles of common laboratory tests used in monitoring and decision-making regarding anticoagulation, thrombosis, and hemostasis can be found in Table 36.8.

Management of Device-Related Severe Hemolysis and Thrombosis
Severe hemolysis and pump thrombosis are of serious concern with MCS devices and require thorough troubleshooting to further complications, although in some scenarios, operative intervention or device change-out is required. In MCS, hemolysis and device thrombosis are commonly discussed in similar contexts, largely because of the associated clinical progression that is commonly seen as the pathogenesis continues from thrombus initiation to complete thrombosis (see Figure 36.5). The workup for confirmation of device thrombosis commonly entails evaluating the device and cardiac function for contributing factors including documentation and alarm history for suction events, power spikes, speed changes, volume status, and arrhythmias. Additional considerations include urinalysis and blood cultures; imaging to evaluate cannula(e) position and obstruction/thrombus by echocardiography or computed tomography (CT); and imaging to evaluate right ventricular function, gas exchange evaluation of the oxygenator for ECLS, or the echocardiographic ramp study in the scenario of left ventricular assist devices (LVADs). The ramp study can provide an indirect evaluation of a potential intra-device thrombus because the VAD itself cannot be viewed internally by imaging. The ramp study evaluates for decreases in left ventricular end-diastolic dimension by echocardiogram during simultaneous increases in LVAD speeds and correlating power consumption. If thrombus were likely, potential obstruction within the VAD would be evidenced by lacking augmentation of VAD flows as well as minimal
decreases in left ventricular end-diastolic dimension despite increasing VAD speeds. Additional investigation into compliance with anticoagulation regimen and goals should be assessed, together with quantifiable hemolysis laboratory values to evaluate the degree of elevation (e.g., LDH and plasma-free hemoglobin).

Although manipulation of the cannulae or changing of the oxygenator can be accomplished with a somewhat lower risk in temporary MCS or ECLS, the management decision for implanted durable MCS devices (LVADs) is more complex. The most definitive option for device thrombosis is surgical change-out of the device. However, surgical intervention comes with many other risks, most notably the risk of bleeding because of reoperation (particularly with a redo sternotomy). Some centers have tried to standardize the thought process for evaluation and treatment of suspected LVAD thrombosis. Therefore, in some scenarios, medical treatment of hemolysis and/or partial pump thrombosis may be pursued to avoid unnecessary surgery or extreme surgical risk. Although this strategy may be successful if the process is identified early, published data of the attempts with alteplase, glycoprotein IIb/IIIa inhibitors, or direct thrombin inhibitors have not shown it to be largely successful.

INFECTION TREATMENT AND PREVENTION IN PATIENTS WITH MCS

The consequence and management of infections in patients with MCS create many clinical challenges beyond the pharmacologic challenges...
described earlier in this chapter. The presence of indwelling or implanted prosthetic material lends itself to greater infectious complexities, and in the case of long-term devices, the driveline care must be consistent and meticulous to avoid seeding infectious risk at this abdominal wound. Infections in these long-term MCS devices have been characterized by ISHLT (Table 36.9).

Furthermore, before placement of the device or for surgical procedures occurring after device placement, antibiotic coverage for surgical prophylaxis for MCS-related or non–MCS-related surgical procedures should account for the site of procedure, previous infections (if VAD), proximity to driveline site or VAD pocket, and any other potential exposure or bacteremia secondary to the procedure. In some circumstances, this requires broader prophylactic antibiotic coverage.\textsuperscript{91}

Beyond the immediate perioperative/periprocedural period of up to 48 hours after device placement, evidence neither supports nor refutes the use of ongoing prophylactic antibiotics owing to indwelling cannulae for MCS, and practice patterns have considerable variability.\textsuperscript{92,93} Nonetheless, consideration for appropriate antimicrobial stewardship practices should be advocated. However, if an infection is identified or suspected, antibiotic coverage should account for the site of suspected infection, previous pathogens and susceptibilities, proximity to driveline site or VAD pocket, and any other potential exposure or bacteremia. Once the source is identified and controlled, treatment duration largely depends on the nature of the infection. However, if the infection is VAD-related or VAD-specific, prolonged (greater than 4 weeks) antimicrobial therapy is commonly used. In addition, because LVAD change-out is not without considerable risk, long-term oral antibiotic suppression therapy may be considered for some infections.

\textbf{FUTURE DIRECTIONS}

Mechanical circulatory support has shown considerable advances through the years; however, the pharmacotherapeutic challenges remain complex and require familiarity among the clinical care team to
provide optimal outcomes. Advances in the future, including transcutaneous power supplies and smaller devices, may help eliminate some of these obstacles. However, ongoing research is needed to help refine recommendations for anticoagulation in MCS, particularly for the ideal management of sedation, analgesia, and antibiotic dosing in ECLS. Although some data can assist in our management today, every opportunity should be taken to provide a more individualized approach through guided therapy with therapeutic drug monitoring and with dosing tailored to known pharmacokinetic alterations. Various organizations are have been involved in the regulation, registry development, and advancement of MCS therapy. For further information, please see the following:

Other Urgencies and Emergencies
Chapter 37 Hypertensive Crisis

Jeremy Flynn, Pharm.D., FCCP, FCCM; Melissa Nestor, Pharm.D., BCPS; and Komal Pandya, Pharm.D., BCPS

LEARNING OBJECTIVES

1. Understand the basic underlying pathophysiology of hypertensive crisis within the context of underlying disease states and etiologies.

2. List the possible organ system dysfunctions that are possible with hypertensive crisis.

3. Describe management options that are preferred and those that should be used with caution.

ABBREVIATIONS IN THIS CHAPTER

ACEI Angiotensin-converting enzyme inhibitor
APH Acute postoperative hypertension
aSAH Aneurysmal subarachnoid hemorrhage
DBP Diastolic blood pressure
ICH Intracerebral hemorrhage
ICU Intensive care unit
MAP Mean arterial pressure
INTRODUCTION

Epidemiology
Hypertension is extremely common with a prevalence of about 25%–30% and affects an estimated 80 million adults in the United States and more than 970 million adults worldwide. Compared with other dietary, lifestyle, and metabolic risk factors, hypertension is the leading cause of death in women and the second leading cause of death in men, behind smoking. In the United States, there is a higher prevalence of hypertension in black populations than in white, Hispanic, and Asian populations. In addition, the prevalence of hypertension in all population groups increases with age. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) classified patients according to systolic blood pressure (SBP) and diastolic blood pressure (DBP) values ([prehypertension (SBP 120–139 mm Hg or DBP 80–89 mm Hg], stage 1 hypertension [SBP 140–159 mm Hg or DBP 90–99 mm Hg], and stage 2 hypertension [SBP of 160 mm Hg or greater or DBP of 100 mm Hg or greater]) and recommended that patients with a diagnosis of stage 1 or 2 hypertension receive pharmacologic management if lifestyle modifications have failed to achieve blood pressure goals. The 2014 report relaxes treatment initiation for the general population 60 years and older to a threshold of SBP of 140 mm Hg or greater or DBP of 90 mm Hg or greater in the absence of other risk factors such as chronic kidney disease, diabetes mellitus, and cerebrovascular disease. Although much of the morbidity and mortality associated with hypertension is attributed to processes developing over time, patients may also present with in hypertensive crisis, placing them at risk of impending or progressive organ damage. Hypertensive crisis has been estimated to occur in 1% of adults with a history of hypertension.
annually; however, the true incidence may be higher, especially given that one investigation showed that 23% of hypertensive crisis cases requiring emergency department management occurred in patients with no history of hypertension.\(^4\)

**Pathophysiology**

Acute blood pressure elevation in hypertensive crisis may be caused by a variety of underlying etiologies, and it may occur in patients with a history of hypertension or in those without. Several different causes of hypertensive crisis exist including, but not limited to, history of essential hypertension, renal disease, pregnancy, endocrine disorders, drug-induced hypertension, autonomic dysfunction, and disorders of the central nervous system.\(^5\) With respect to patients with essential hypertension, situations such as inadequately controlled hypertension, medication nonadherence, and lack of consistent medical follow-up are common patient-specific scenarios that lead from essential hypertension to hypertensive crises. Although the overall precipitating causes may differ, the underlying pathology of hypertensive crisis can be defined by how it affects the regulation of hemodynamic parameters. Systolic blood pressure is determined by cardiac output, a product of stroke volume and heart rate, and systemic vascular resistance, a function of peripheral vascular resistance and renal vascular resistance.\(^6\) Marked hypertension is often associated with increased levels of vasoactive substances, such as norepinephrine, antidiuretic hormone, and the renin-angiotensin-aldosterone system (RAAS), or by direct pressure-related effects on the vasculature.

Increased blood pressure caused by an increased systemic vascular resistance can be mediated by an increase in circulating endogenous catecholamines. Vasoconstriction and increased heart rate mediated by increased norepinephrine and epinephrine, whether as a primary disease process or as a secondary response, can contribute to hypertensive crisis.\(^7\) Renin is typically released from the kidneys as a response to a perceived decreased arterial blood volume, and once in circulation, it catalyzes the conversion of angiotensinogen, a liver-derived zymogen, to angiotensin I. Circulating angiotensin I is converted
by angiotensin-converting enzyme to active angiotensin II, which has several mechanisms by which it affects blood pressure by augmenting circulating blood volume and inducing vasoconstriction. Angiotensin II acts directly on vascular smooth muscle to induce vasoconstriction, thus increasing systemic vascular resistance. Increased circulating blood volume is influenced by angiotensin II because it enhances the release of aldosterone, increasing sodium reabsorption as well as increasing secretion of antidiuretic hormone. Angiotensin II also plays a role in smooth muscle cell growth and migration, but the role of this effect in acute hypertensive crisis remains unclear. In sustained or severe hypertension, stressed vascular endothelium may be overwhelmed and unable to balance vasoconstrictive processes with compensatory nitric oxide and prostacyclin, continuing the cycle of ongoing hypertension. This loss of endothelial function is not well understood; however, proinflammatory processes and pressure-related endothelial damage are likely involved in furthering vasoconstriction.

**CLINICAL PRESENTATION**

Hypertensive crises can be subdivided into hypertensive urgency and emergency. Presence of end-organ damage is the distinction between the two, with end-organ damage being present with hypertensive emergency. Clinical presentation varies from patient to patient. Organ dys-function is uncommon with DBPs less than 130 mm Hg (except in children and in pregnancy). One recent study by Zampaglione and colleagues found single-organ involvement in 83%, two-organ involvement in 14%, and three- or more organ involvement in only 3% of hypertensive emergencies (Table 37.1). In another study examining the prevalence of various end-organ complications in patients with hypertensive crisis, neurologic complications—specifically cerebral infarctions—were the most prevalent, followed by acute heart failure and acute myocardial infarction. Standard treatment of a hypertensive crisis in the intensive care unit (ICU) involves continuous blood pressure monitoring and parenteral administration of an antihypertensive agent.
Blood Pressure

Hypertensive emergencies are characterized by severe elevations in blood pressure (greater than 180/120 mm Hg) complicated by evidence of impending or progressive target organ dysfunction. Examples include hypertensive encephalopathy, intracerebral hemorrhage, acute myocardial infarction, acute left ventricular failure with pulmonary edema, unstable angina pectoris, dissecting aortic aneurysm, and eclampsia. Hypertensive urgencies are situations associated with severe elevations in blood pressure without progressive target organ dysfunction. Examples include upper levels of hypertension associated with severe headache, shortness of breath, epistaxis, or severe anxiety. Most of these patients present as nonadherent or inadequately treated patients with hypertensive emergencies, often with little or no evidence of target organ damage.4,11

Optic Fundi
Retinopathy is a hallmark symptom of hypertensive crisis and is present in many patients on presentation. Typical findings on optic examination include hard exudates, hemorrhages, and papilledema. Retinal hemorrhages are a result of necrosis of the capillary and precapillary arteriolar walls. This endothelial necrosis leads to leakage and deposition of plasma proteins in the posterior retina, which manifests as hard exudates. Papilledema is defined as a swelling of the optic disc and, in the past, was associated with a poor prognosis; however, this finding is no longer a prognostic indicator. With blood pressure management, retinal lesions may be reversed.4,11-13

Cardiovascular
Hypertensive crisis can result in acute heart failure and lead to pulmonary edema. This can be attributed to increases in preload and afterload. Acute heart failure is the presenting symptom in 11%–15% of patients. Common cardiovascular findings in these patients may include underlying ischemic heart disease, acute myocardial infarction, angina symptoms, and left ventricular hypertrophy. Aortic dissection is less common, but when it does occur, it is life threatening.2,11,13

Neurologic
Neurologic symptoms are often the presenting complaint in hypertensive crisis. More than 60% of patients present with headaches, and up to 28% experience dizziness.4 Cerebrovascular events occur in 7% of patients with hypertensive crisis and include transient or focal cerebral ischemia as well as cerebral and subarachnoid hemorrhage. Hypertensive encephalopathy is characterized by headache, nausea, vomiting, and blurred vision. Other symptoms may include impaired cognition, generalized seizures, and
cortical blindness. Hypertensive encephalopathy is likely to arise from loss of autoregulation in cerebral vessels as the result of severe increases in SBP. Normally, cerebral blood flow is maintained constant despite fluctuations in a range of perfusion pressures. With chronic hypertension, adaptive processes allow cerebral blood flow to be maintained at a higher perfusion pressures and thereby prohibit or attenuate the severity of hypertensive encephalopathy during sudden increases in blood pressure. At very high pressures, this autoregulatory process breaks down. This may occur when the blood pressure is greater than 160/100 mm Hg in previously normotensive patients. In patients with chronic hypertension, it rarely develops until the blood pressure is greater than 200/120 mm Hg. Pathologic findings include cerebral microinfarctions, petechial hemorrhages, and cerebral edema. As the blood pressure is reduced, fluid extravasation decreases, and cerebral autoregulation gradually normalizes. In patients with chronic hypertension, autoregulation may take time to reestablish. Therefore, depending on the clinical scenario, blood pressure should be lowered slowly in severely hypertensive subjects with chronic hypertension to avoid precipitating cerebral ischemia.²,¹¹-¹⁴

Renal
Renal involvement is also a common complication. Non-nephrotic–range proteinuria is commonly associated with elevated serum creatinine concentrations. Increased serum creatinine (greater than 2.3 mg/dL) occurs in 31% of patients at presentation. Overt nephrotic syndrome is uncommon. Urinalysis may be useful in differentiating if kidney injury is acute versus chronic in nature. Hypokalemic metabolic alkalosis may develop as a result of volume depletion and secondary hyperaldosteronism. Plasma renin activity and aldosterone are increased in most cases.²,¹³,¹⁵

Hematologic
Microangiopathic hemolytic anemia, thrombocytopenia, increased fibrin degradation, and increased fibrinogen are commonly seen. Erythrocyte
sedimentation rate is often elevated because of renal failure and anemia.\textsuperscript{16}

\section*{DIAGNOSTIC CONSIDERATIONS AND CLINICAL EVALUATION}

Early triage to emergency departments to initiate appropriate therapeutic interventions for these patients is critical to affecting morbidity and mortality. Patients presenting with hypertensive crisis may represent up to 25\% of all patient visits to busy urban emergency departments.\textsuperscript{2} Evaluation of patients with hypertension involves assessment of lifestyle, identification of risk factors and comorbidities that may affect prognosis and guide treatment, identification of potential causes of high blood pressure, and assessment for the presence of target organ damage and cerebrovascular disease. Patient evaluation is made through ascertaining medical history, physical examination, routine laboratory tests, and other diagnostic procedures. The physical examination should include an appropriate measurement of blood pressure with verification in the contralateral arm; examination of the optic fundi; calculation of BMI (body mass index); auscultation for carotid, abdominal, and femoral bruits; palpation of the thyroid gland; thorough examination of the heart and lungs; examination of the abdomen for enlarged kidneys, masses, distended urinary bladder, and abnormal aortic pulsation; palpation of the lower extremities for edema and pulses; and neurologic assessment.\textsuperscript{12,14,16}

Patients with hypertensive crisis should be admitted to an ICU for continuous hemodynamic monitoring and administration of intravenous antihypertensive agents. According to the JNC-7 guidelines, the initial goal of therapy in hypertensive emergencies is to reduce the mean arterial blood pressure by no more than 20\%–25\% (within minutes to 1 hour) and then, if stable, to an SBP of 160 mm Hg and/or a DBP of 100–110 mm Hg during the next 2–6 hours. More aggressive blood pressure reductions may precipitate and perpetuate renal, cerebral, or coronary ischemia. This recommendation is based on the body’s ability
to autoregulate tissue perfusion in the brain, heart, and kidneys. If this level of blood pressure reduction is well tolerated, further gradual reductions toward a goal blood pressure can be executed in the next 24–48 hours. There are exceptions to this treatment strategy. There is no clear evidence from clinical trials that patients with an acute ischemic stroke benefit from the use of immediate intravenous antihypertensive treatment unless it is lowered to enable the use of thrombolytic agents. In addition, patients with aortic dissection should have their SBP lowered to less than 120 mm Hg as quickly as possible, if tolerated. It is imperative to ensure appropriate monitoring for signs or symptoms of ischemia-related end-organ system deterioration that may accompany changes in SBP, DBP, or mean arterial pressure (MAP).12,14,16

The JNC-7 criteria for accurate blood pressure measurements require that two readings be taken 5 minutes apart with the patient at rest in a seated and standing position.2 Recall that there is a statistical tendency for repeat measurements to regress toward the mean of measurements. A study of 195 consecutive patients with hypertension in an emergency department validated this mathematical principle and documented a mean decline of 11.6 mm Hg in repeated DBP readings. Unexpectedly high blood pressure readings should be repeated because a measurement error can occur from the misapplication of the sphygmomanometer cuff, use of an inappropriately sized cuff, or operator error. In addition, consider whether the hypertension is reactive in nature. If the hypertension is caused by anxiety, pain, or use of sympathomimetics (such as decongestants or cocaine) or by withdrawal states (e.g., withdrawal from alcohol or antihypertensive medication), addressing the underlying condition is an imperative part of management. Urine toxicology for cocaine can be helpful in select, high-risk patient populations.

A thorough patient history is needed to determine concomitant disease states and home blood pressure readings, if possible. Furthermore, elucidating the patient’s home medications and medication adherence is essential. This history should include prescription medications, over-the-counter medications, and
recreational drugs as well as any supplements because any of these may contribute to the patient’s clinical picture.\textsuperscript{11}

Neurologically, patients should be evaluated for any symptoms associated with ischemic or hemorrhagic stroke or hypertensive encephalopathy. A funduscopic optical examination to assess for papilledema, hemorrhage, or exudates within the eye may be indicated. A thorough cardiovascular assessment is also necessary. Crucial components include auscultation for new murmurs associated with aortic insufficiency or dissection as well as checking for mitral regurgitation, which could be associated with ischemia. A gallop could indicate acute heart failure. The lung fields should be auscultated to check for crackles suggestive of pulmonary edema.

Laboratory tests should be assessed to validate physical examination findings. These should include serum electrolytes, serum creatinine, and a complete blood cell count with peripheral smear. A 12-lead electrocardiogram should be ascertained to determine myocardial ischemia or left ventricular hypertrophy. A chest radiograph could help determine the presence of pulmonary edema, widened mediastinum, or cardiac enlargement. A urine analysis may be helpful in assessing for casts and proteinuria. More extensive testing for identifiable causes of hypertensive crisis are not usually indicated unless blood pressure control is not achieved or unless the clinical and routine laboratory evaluation strongly suggests an identifiable secondary cause (i.e., vascular bruits, symptoms of catecholamine excess, unprovoked hypokalemia).

In addition, two emerging risk factors may be evaluated, particularly in those with cerebrovascular disease but without other risk factor abnormalities: (1) high-sensitivity C-reactive protein, a marker of inflammation; and (2) homocysteine. Current data do not highlight the role of these factors in the management of hypertensive crisis, but they may come to play a role in chronic management and risk assessment.

**General Therapeutic Approach**

In patients with hypertensive urgencies, blood pressure is lowered over 24–48 hours, usually with oral medication. Some patients with
hypertensive urgencies may respond to treatment with an oral, short-acting agent such as captopril, labetalol, or clonidine together with a period of observation. However, there is no evidence to suggest that failure to aggressively lower blood pressure in these patients while admitted to the emergency department is associated with any increased short-term risk to these patients. Furthermore, they may benefit from adjustment in their current antihypertensive therapy or reinstitution of medications if nonadherence is a problem. Patients should be discharged from the emergency department with a confirmed follow-up visit within 24–48 hours postdischarge. The term urgency may lead to overly aggressive antihypertensive treatment with intravenous drugs or even oral agents to rapidly lower blood pressure. However, this practice is not without risk. Oral loading doses of antihypertensive agents may lead to accumulation of drug, which may result in hypotension after discharge from the emergency department. Patients who continue to be nonadherent often return to the emergency department within weeks.\textsuperscript{13,14,16}

Patients with hypertensive emergency require immediate control of the blood pressure to attenuate end-organ damage. Blood pressure in patients with hypertensive emergencies should be treated in a controlled fashion in an ICU. Continuous blood pressure monitoring should be considered in these patients to assist in appropriate titration of therapeutic agents. Type of monitoring may vary from blood pressure cuff to more invasive intra-arterial blood pressure monitoring. Choice of monitoring mechanism is complex and may depend on the type of patient, cause of hypertensive crisis, and agents used to control hemodynamics. Once therapeutic end points have been achieved, the patient can be initiated on a regimen of oral maintenance antihypertensive therapy.

\section*{Medical Therapies}

\textbf{Calcium Channel Antagonists}
Calcium channel antagonist agents or calcium channel blockers have clinical application in a variety of cardiovascular disease states.
Although there are six known types of calcium channels, only the L- and T-type channels are thought to have effects relevant to cardiovascular disease. The clinical role of T-type calcium channel antagonism remains undefined and is an area for further research. L-type calcium channel antagonists can be subdivided into three major subclasses: dihydropyridines (nicardipine and clevidipine), phenylalkylamines (verapamil), and benzothiazepines (diltiazem).

L-type calcium channels are widespread in a variety of tissues including the cardiovascular system, neuronal, and secretory tissue. Calcium channel antagonists inhibit calcium influx during depolarization and result in end effects such as decreased vascular constriction, decreased atrioventricular nodal conduction, and negative inotropy—though these are strongly influenced by calcium channel antagonist structure and subclass. The classical targets for calcium channel antagonists are the Ca\(\text{v}_{1}\) L-type receptors found on myocardial and vascular smooth muscle, which can reach the receptor either by the open channel or though the lipid membrane of a closed channel. Verapamil and diltiazem are charged at physiologic pH, enter calcium channels in the open state, and have increased activity on cardiac L-type channels. This results in the decreased atrioventricular node transduction and negative inotropy associated with these agents. In contrast, dihydropyridine agents are more lipophilic, exerting their action on closed or inactive calcium channels with a higher affinity for vascular calcium channels. For this reason, we will now focus on dihydropyridine calcium channel antagonists, of which two are currently available in intravenous formulations: nicardipine and clevidipine.

**Nicardipine**

Nicardipine is a dihydropyridine calcium channel antagonist, indicated for short-term management of hypertension. Nicardipine exerts its antihypertensive action by selective dilation of arterial and coronary vascular smooth muscle with no significant venodilatory effects. A fairly quick onset of action of 5–15 minutes is observed with a duration of antihypertensive effects of 4–6 hours and a terminal half-life of 14 hours, prolonged in patients with hepatic impairment (Table 37.2).
Nicardipine has linear kinetics, is highly (greater than 95%) protein bound, and is metabolized by the liver by the cytochrome P450 (CYP) enzymes, primarily by CPY2C8, CYP2D6, and CYP3A4. No pharmacokinetic differences have been seen between younger individuals and those older than 65 years. Nicardipine is contraindicated in patients with advanced aortic stenosis.\textsuperscript{11,20}

Nicardipine should be initiated at 5 mg/hour and increased by 2.5 mg/hour every 15 minutes until goal blood pressure is attained, with a maximum of 15 mg/hour. Once goal blood pressure is achieved, a taper of 3–5 mg/hour every 15 minutes should be tried, as tolerated. Nicardipine is available as a premixed infusion of either 0.1 or 0.2 mg/mL (in either dextrose or saline solutions) or as a concentrated solution (2.5 mg/mL), which is recommended to be diluted to a concentration of 0.1 mg/mL in buffered solutions for a pH of 3.7–4.7 and 3.5, respectively.\textsuperscript{21,22} Although typically well tolerated, adverse events associated with nicardipine are typically those associated with vaso-dilation such as headache, hypotension, and tachycardia. To avoid potential peripheral vein irritation, manufacturers recommend changing infusion sites every 12 hours.

**Clevidipine**

Clevidipine is a third-generation dihydropyridine calcium channel antagonist, also indicated for short-term management of hypertension. Clevidipine exerts its antihypertensive action by a selective effect of arterioles, with minimal effects on venous capacitance vessels and cardiac preload. Clevidipine has a rapid onset of action, about 2–4 minutes, with a terminal half-life of about 15 minutes because it is metabolized by esterases predominantly in the blood and extravascular tissues (Table 37.2). Clevidipine is highly protein bound (greater than 99%), and although data are limited, no drug-drug interactions are likely because it is hydrolyzed by esterases, and neither clevidipine nor its metabolites are expected to interfere with CYP enzymes at therapeutic concentrations. No dose adjustments are recommended in the setting of hepatic or renal impairment, though it may be prudent to initiate dosing at the lower end of the recommended range in the older adult population. Clevidipine is generally well tolerated, showing
minimal to modest reflex tachycardia and an increase in serum triglyceride concentrations in some study populations (decreased with the discontinuation of clevidipine).\textsuperscript{23}

aSAH = aneurysmal subarachnoid hemorrhage; BP = blood pressure; ICH = intracerebral hemorrhage; IM = intramuscularly; IV = intravenously; q = every.

It is recommended to initiate clevidipine at a dose of 1–2 mg/hour, with a doubling of the dose at short (90 seconds) intervals initially, lengthening to every 5–10 minutes as goal blood pressure is attained. Clinical experience is limited with doses above 32 mg/hour. Clevidipine is available for intravenous use in a 20% lipid emulsion (2 kcal/mL) and, like similar formulations, contraindicated in patients with allergies to soybeans/soy products or eggs/egg products. Because of the lipid vehicle, doses greater than 1,000 mL/day (an average of 21 mg/hour/day) are not recommended. In addition, there is limited experience with treatment courses exceeding 72 hours in duration.
Caloric intake and triglyceride concentrations should be assessed for patients receiving clevidipine. Clevidipine may be infused by central or peripheral venous access, and because of the risk of bacterial growth in the lipid medium, the vial must be changed every 12 hours.\textsuperscript{23,24}

**Angiotensin-Converting Enzyme Inhibitors**

**Enalaprilat**

Enalaprilat is the active form of the prodrug enalapril and is the only angiotensin-converting enzyme inhibitor (ACEI) available in an intravenous formulation. Like all ACEIs, enalaprilat prevents the conversion of angiotensin I to angiotensin II as part of the RAAS. This system is vital in maintaining blood pressure, electrolyte balance, and volume status. Renin, released by juxtaglomerular cells in the afferent arterioles in response to decreased renal per-fusion and/or sodium load, cleaves angiotensinogen to angiotensin I, which is then converted to angiotensin II by angiotensin-converting enzyme, the target for ACEI agents. Angiotensin II stimulates G-protein angiotensin II type 1 receptors, resulting in arteriolar constriction, including marked efferent arteriole constriction, release of aldosterone and antidiuretic hormone, and increased sympathetic nervous system activity, and it has a role in cardiac mitogenesis and remodeling. Angiotensin-converting enzyme inhibitors also prevent the breakdown of substance P and bradykinin, a vasodilator.\textsuperscript{25,26}

Enalaprilat may be given in hypertensive crisis with an initial dose of 1.25 mg intravenously every 6 hours, given as a slow intravenous push over 5 minutes, with antihypertensive effects seen as quickly as 10–15 minutes after infusion, a maximal onset in 0.5–1 hour, and duration of action of 12–24 hours (Table 37.2).\textsuperscript{27,28} Although this is advantageous in maintenance therapy, allowing for daily dosing of oral enalapril, this long duration of action may be detrimental in patients experiencing hypotension after drug administration. Also of note is that the baseline degree of RAAS activity may affect patient response to enalaprilat. The degree of blood pressure lowering in patients with hypertensive crisis has been correlated with plasma renin concentration, with a
higher degree of response in patients having a high degree of RAAS activity.\textsuperscript{29}

Enalaprilat is primarily excreted unchanged in the urine (61\%) and feces (33\%), with a recommended lower initial dose of 0.625 mg in patients with a CrCl of less than 30 mL/minute/1.73 m\textsuperscript{2} and care taken in patients on hemodialysis. Renal impairment is associated with enalaprilat use, mediated by its overall hypotensive effects and specifically alteration of angiotensin II–mediated efferent arteriolar vasoconstriction, more often observed in patients with baseline renal compromise. In addition, enalaprilat should be used with caution in patients with aortic stenosis or hyperkalemia, and it is contraindicated in pregnant patients and patients with a history of hereditary or idiopathic angioedema.\textsuperscript{26,28,30} Reported adverse effects with enalaprilat include cough, angioedema, and hypotension. The inhibition of bradykinin and substance P is thought to relate to the incidence of ACEI-associated cough. Angioedema is a relatively rare (0.1\%–0.3\% incidence) but potentially life-threatening adverse effect of ACEI therapy, typically manifesting with edema of the face, tongue, and throat with reports of death from laryngeal edema reported. Elevated bradykinin is also thought to be associated with angioedema, more commonly seen in women and black patients than in non-black patients.\textsuperscript{26,31,32}

\textbf{Vasodilators}

\textbf{Sodium Nitroprusside}

Functionally, sodium nitroprusside is a nitric oxide donor that is converted to a free radical that activates endovascular guanyl cyclase. This results in myosin dephosphorylation and subsequent vascular smooth muscle relaxation. Sodium nitroprusside acts on arteriolar and venous smooth muscle, thereby reducing both preload and after-load. Unpredictable decreases in blood pressure are often seen in patients with hypovolemia or diastolic dysfunction because of sodium nitroprusside effects on preload. In patients with left ventricular failure, decreases in preload may result in a decreased cardiac index,
whereas reductions in afterload prohibit the reflexive tachycardia that would normally occur with a drop in cardiac output. Sodium nitroprusside infusion is typically initiated as a continuous intravenous infusion with a starting infusion rate of 0.3–0.5 mcg/kg/minute, with increases in increments of 0.5 mcg/kg/minute to achieve hemodynamic targets (Table 37.2). The treatment duration should be as short as possible, and to avoid doses exceeding 2 mcg/kg/minute. The dosage requirement in older adult patients is typically lower than in younger patients. The exact mechanism of this increased sensitivity is unknown but is thought to be related to diminished baroreceptor reflex activity, resistance of cardiac adrenergic receptors to catecholamine stimulation, or variations in the direct vasodilating effects of sodium nitroprusside. It has an immediate onset and duration of effect of 2–3 minutes. Tachyphylaxis may develop while using this agent. More severe toxicity associated with sodium nitroprusside is a result of the release of cyanide with interference with cellular respiration. Sodium nitroprusside is metabolized into cyanogen, which is converted to thiocyanate by the enzyme thiosulfate sulfur-transferase. It contains 44% cyanide by weight. Cyanide is released non-enzymatically from sodium nitroprusside, the amount generated being dependent on the dose of sodium nitroprusside administered. Cyanide toxicity may manifest as an unexplained cardiac arrest, coma, encephalopathy, convulsions, hyperreflexia, blurred vision, tinnitus, and irreversible focal neurologic changes. Because free cyanide radicals may bind and inactivate tissue cytochrome oxidase, thereby preventing oxidative phosphorylation, increased cyanide concentrations may also cause tissue anoxia, anaerobic metabolism, and lactic acidosis. Patients receiving sodium nitroprusside with symptoms of central nervous system dysfunction, cardiovascular instability, and increasing metabolic acidosis should be assessed for cyanide toxicity. The current laboratory monitoring methods for cyanide toxicity may be insensitive, given that the accuracy of laboratory results relies on proper storage conditions of blood samples. However, if clinical suspicion of toxicity is high, initiating treatment can be considered before receiving laboratory results. In addition, a rise in serum
thiocyanate concentrations is a late-occurring event and is not directly related to cyanide toxicity. Red blood cell cyanide concentrations may be a more reliable method of monitoring for cyanide toxicity, but this is not currently widely available. A red blood cell cyanide concentration above 40 nmol/mL correlates with detectable metabolic changes. Cyanide toxicity is unusual until the total dose exceeds 300 mg or the infusion rate is above 20 mcg/kg/minute, although toxic cyanide concentrations have been seen at various infusion rates. In general, the risk of toxicity increases incrementally with increasing doses. Concentrations greater than 200 nmol/mL are associated with severe clinical symptoms, and concentrations greater than 400 nmol/mL are considered lethal. To avoid potential toxicity, the treatment duration with sodium nitroprusside should be as short as possible, and the infusion rate should be no greater than 2 mcg/kg/minute. The concentrations should be maintained below 10 mg/dL to avoid thiocyanate toxicity. When toxicity is confirmed or suspected, sodium nitroprusside administration should be discontinued. An infusion of thiosulfate may be used in patients receiving higher dosages (4–10 mcg/kg/minute) of sodium nitroprusside. For sodium nitroprusside infusions of 4–10 mcg/kg/minute or greater or infusions longer than 30 minutes, thiosulfate can be coadministered at a 10:1 sodium nitroprusside/thiosulfate ratio to avoid cyanide toxicity.

Furthermore, sodium nitroprusside comprises a ferrous ion center complexed with five cyanide moieties, which may react with methemoglobin and produce cyanomet-hemoglobin. Normal methemoglobin concentrations can bind the cyanide released from 18 mg of sodium nitroprusside. The total dose of sodium nitroprusside required to cause 10% methemoglobinemia is greater than 10 mg/kg (greater than 10 mcg/kg/minute for more than 16 hours).

Other methods of cytotoxicity may arise through the release of nitric oxide, with hydroxyl radical and peroxynitrite generation leading to lipid peroxidation. Sodium nitroprusside activates guanylate cyclase, which stimulates the formation of cyclic guanosine monophosphate that relaxes smooth muscle.

Thiocyanate is also toxic; however, it is 100-fold less toxic than
cyanide. It is eliminated by renal excretion, with a half-life of 3–7 days. Sodium nitroprusside infusions of 2–5 mcg/kg/minute for 7–14 days may be needed to generate thiocyanate toxicity. Nonspecific symptoms of thiocyanate toxicity include fatigue, tinnitus, nausea, and vomiting; clinical signs include hyperreflexia, confusion, psychosis, and miosis.

Normally, adults can detoxify 50 mg of sodium nitroprusside using existing stores of sulfur, but malnutrition, surgery, diuretic use, or other factors can reduce this capacity. Cyanide is metabolized in the liver to thiocyanate and requires thiosulfate to occur. Thiocyanate is 100 times less toxic than cyanide. Thiocyanate is excreted through the kidneys. Cyanide removal therefore requires adequate liver function, adequate renal function, and adequate bioavailability of thiosulfate. Cyanide is known to interfere with cellular respiration. Friederich and colleagues showed that lipid peroxidation in the substantia nigra of rats occurs after the administration of sodium nitroprusside. Lipid peroxidation has also been shown in hepatocytes. In addition, sodium nitroprusside causes concentration- and time-dependent ototoxicity.

As an alternative to thiosulfate, hydroxycobalamin (vitamin B₁₂) received marketing approval in 2006 from the U.S. Food and Drug Administration (FDA) for the treatment of known or suspected cyanide poisoning at a starting dose of 5 g administered by intravenous infusion over 15 minutes.

Nitroglycerin
Nitroglycerin is primarily a venodilator; however, arteriodilation of vascular smooth muscle can occur at high doses. Regarding mechanism of action, nitroglycerin is converted to nitric oxide, which activates guanylate cyclase and stimulates the production of cyclic GMP. This produces venous smooth muscle relaxation and reduction in preload. In volume-depleted patients, a reduction in preload reduces cardiac output, which may be undesirable in patients with compromised myocardial, cerebral, or renal perfusion. Severe hypotension and reflex tachycardia have been reported in these patients quickly after initiating a nitroglycerin infusion. For the treatment of hypertensive crisis,
nitroglycerin is initiated at a rate of 5 mcg/minute by continuous intravenous infusion. The dose may be titrated in increments of 5 mcg/minute every 3–5 minutes to an infusion rate of 20 mcg/minute. If blood pressure response is inadequate to this infusion rate, the dose may be increased by 10 mcg/minute every 3–5 minutes, up to a maximum rate of 200 mcg/minute (Table 37.2). If a weight-based dosing algorithm is used, the usual starting dose is 0.2 mcg/kg/minute. The dose may be increased in increments of 0.2–0.5 mcg/kg/minute every 3–5 minutes to a maximum dose of 2 mcg/kg/minute. Onset of action of nitroglycerin is within 2–5 minutes, and the duration of action is 5–10 minutes, with a half-life of 1–3 minutes. Tolerance of the hemodynamic effects of nitroglycerin limits its clinical utility. Headache is the most common adverse effect, and methemoglobinemia is a rare complication of prolonged infusions. It can also cause hypotension and reflex tachycardia. Administration of low-dose nitroglycerin (approximately equal to 60 mcg/minute) as an adjunct to other intravenous antihypertensive agents may be useful for patients with hypertensive emergencies associated with acute coronary syndromes or acute pulmonary embolism.

Hydralazine
Hydralazine is a peripheral, direct-acting vasodilator that relaxes arteriolar smooth muscle by inhibiting calcium ion release from the sarcoplasmic reticulum. The specific mechanism of action is not well understood, but proposed mechanisms include inhibition of calcium release caused by inositol trisphosphate and reducing calcium turnover. There is also a potential for direct myocardial effect from increased influx of calcium into the sarcolemma that may be a result of the stimulation of β-adrenergic receptors. Other proposed mechanisms of action include membrane hyperpolarization and inhibition of oxidase formation. The arteriodilation reduces cardiac afterload and may improve cardiac function in patients with heart failure.

The initial dose of hydralazine is a 10-mg bolus by slow intravenous administration every 4–6 hours as needed to attain target blood
pressure (Table 37.2). Repeated bolus doses generally should not exceed 20 mg, although they may be increased to 40 mg. Blood pressure begins to decrease within 10–30 minutes, and the fall can last from 2–4 hours. Hydralazine may also be given intramuscularly, which may be advantageous in patients with poor vasculature making it difficult to obtain intravenous access. The onset of action post-intravenous administration is 10–20 minutes, and its duration of action of 1–4 hours. After intramuscular or intravenous administration, a latency period of 5–15 minutes is followed by a progressive and often precipitous fall in blood pressure that can last up to 12 hours post-administration. Although the circulating half-life of the drug is only about 3 hours, the context-sensitive half-life of activity on blood pressure is about 100 hours. Although the mechanism behind this finding is unclear, it may be a result of active metabolites, arteriolar endothelial tissue binding, or a prolonged effect on endothelium-derived relaxing factor. Because of its prolonged and unpredictable antihypertensive effects and its inability to be titrated efficiently, hydralazine is best avoided in the management of hypertensive crises and is not usually considered a first-line agent for the management of hypertensive crisis.

Adrenergic-Receptor Antagonists

Esmolol

Esmolol is a cardioselective \( \beta_1 \)-adrenergic antagonist with a rapid onset of action and a short duration of action. It is a negative inotrope and chronotrope. Because it is a \( \beta_1 \)-cardioselective drug, it pairs well with a direct-acting \( \alpha \)-adrenergic vasodilator such as phentolamine because esmolol possesses no direct vasodilatory actions. A loading dose of esmolol can be given as a 0.5- to 1-mg/kg loading dose over 1 minute, followed by initiation of an infusion at 50 mcg/kg/minute (Table 37.2). The bolus dose can be repeated. The infusion can be titrated in 25-to 50-mcg/kg/minute increments as needed to a maximum of 300 mcg/kg/minute. The onset of action is about 1 minute with a terminal half-life of 9 minutes and a duration of action of 10–20 minutes. The drug is rapidly metabolized by erythrocyte esterases; thus, concomitant
anemia may prolong the duration of effect.\textsuperscript{16,43,44} One significant indication for esmolol is to attenuate the sympathetic discharge seen with severe postoperative hypertension, given that cardiac output, heart rate, and blood pressure are increased.\textsuperscript{45} Esmolol is also safe in the setting of myocardial ischemia.\textsuperscript{46} Patients should be closely monitored for bradycardia, which may occur more often in older adults. If bradycardia occurs, the infusion should be discontinued, and the effects of esmolol on heart rate are eliminated within 20 minutes. Esmolol reduces cardiac index and may worsen or exacerbate the symptoms of patients with acute heart failure. Patients with reactive airway disease should be monitored for exacerbation, though several studies have shown that esmolol, being a cardioselective drug, is well tolerated in patients with pulmonary disease.\textsuperscript{47} Contraindications to esmolol use include concurrent β-blocker therapy, bradycardia, and acute decompensated heart failure. Accidental overdoses of esmolol caused by dilution errors have been reported, which have resulted in fatalities attributed to bolus doses of 625–2500 mg (12.5–50 mg/kg). Premixed injection solutions are available and may help mitigate such dosage errors.

**Labetalol**
Labetalol is a combined \(\alpha_1\)- and nonselective \(\beta\)-adrenergic receptor antagonist. Pharmacodynamically, its action is primarily mediated by \(\beta\)-blockade, with an \(\alpha\)- to \(\beta\)-receptor activity ratio of 1:7 when given intravenously.\textsuperscript{15} Unlike cardioselective \(\beta\)-blockers, which decrease cardiac output, labetalol maintains cardiac output because \(\alpha_1\)-blockade minimizes the reductions in cardiac output seen with \(\beta\)-blockade alone. It also reduces peripheral vascular resistance without diminishing peripheral blood flow, thereby maintaining cerebral, renal, and coronary blood flow. Given that labetalol has little effect on cerebral circulation, it is not associated with increased ICP. Because it is a nonselective \(\beta\)-blocker, labetalol should be used with caution in patients with reactive airway disease or chronic obstructive pulmonary disease. It may exacerbate or precipitate acute decompensated heart failure and should not be used in patients with second- or third-degree
atrioventricular block or bradycardia.\textsuperscript{48}

Labetalol can be given as an intravenous bolus, with incrementally larger doses should repeat dosing be required, until the desired hemodynamic state is achieved. The patient is less likely to respond if no response is observed after a cumulative dose of 300 mg is given (\textbf{Table 37.2}). An intravenous loading dose of labetalol 10–20 mg typically precedes either an infusion or ongoing bolus doses of labetalol. As a single bolus dose, labetalol has an onset of action of 2–5 minutes, with a duration of action of 2–4 minutes.\textsuperscript{16} Incremental bolus doses of 20–80 mg every 10 minutes can be continued until the target blood pressure is attained. Labetalol may also be administered as a continuous intravenous infusion initiated at 0.5–1 mg/minute, adjusted by 0.5–1 mg/minute every 30 minutes until the target blood pressure is attained. Intravenous bolus doses of 1–2 mg/kg have resulted in clinically significant decreases in blood pressure; these should therefore be avoided, if possible. The duration of effect with repeated sequential bolus doses or infusions is 2–4 hours, with an elimination half-life of 5.5 hours.

\textbf{Phentolamine}

Phentolamine is a competitive antagonist of peripheral $\alpha_1$- and $\alpha_2$-receptors and antagonizes the effects of epinephrine and norepinephrine at these receptors, resulting in vasodilation. Furthermore, it has positive inotropic and chronotropic effects on the heart as a result of its $\alpha_2$-blockade. It is generally used to treat hypertensive emergencies induced by catecholamine excess. Examples of such disorders include pheochromocytoma, interactions between monoamine oxidase inhibitors and other drugs or food, cocaine toxicity, amphetamine overdose, and cloni-dine withdrawal.\textsuperscript{11,49} Phentolamine is initiated as an intravenous bolus dose of 5–15 mg (\textbf{Table 37.2}). Its onset of action is 1–2 minutes, with a duration or action of 10–30 minutes. It should be used with caution in those with coronary artery disease because it can potentiate angina symptoms or myocardial infarction. Tachycardia, flushing, and headache are also commonly occurring adverse effects. The compensatory tachycardia can be
ameliorated by administering an intravenous β-blocker.²

Fenoldopam
Fenoldopam is a dopamine type 1 receptor agonist in the periphery with no activity on dopamine type 2 receptors.⁵⁰ It is 10 times more potent at renal dopamine type 1 receptors than dopamine. Agonism of postsynaptic dopamine type 1 receptors results in vasodilation of peripheral arteries as well as the renal and mesenteric vasculature.

Fenoldopam is typically initiated as a continuous intravenous infusion with a starting rate of 0.1–0.3 mcg/kg/minute. The infusion rate may be titrated in increments of 0.05–0.1 mcg/kg/minute every 15 minutes until the target hemodynamics are achieved, to a maximal infusion rate of 1.6 mcg/kg/minute (Table 37.2).¹¹ Data are limited regarding the use of fenoldopam in patients older than 65 years. Fenoldopam should be initiated cautiously in the older adult, usually starting at the low end of the dosing range. The onset of action is less than 5 minutes with a half-life of 9.8 minutes.²,¹⁵,⁵⁰ Adverse effects associated with fenoldopam include headache, flushing, tachycardia, and dizziness. A dose-related increase in intraocular pressure is also possible; thus, fenoldopam should be administered with caution in patients with narrow-angle glaucoma. The drug formulation contains sodium metabisulfate, which should be avoided in patients with an allergy to sulfites.⁵⁰

The overall effect of this vasodilation is a lowering of blood pressure and total peripheral resistance while preserving renal blood flow. Fenoldopam has been shown to improve creatinine clearance, urine flow rates, and sodium excretion in patients with severe hypertension with both normal and impaired renal function. The effects of fenoldopam on renal function were assessed in a meta-analysis involving patients from 16 randomized controlled trials. Authors evaluated the renal-protective properties of fenoldopam in a variety of settings. Fenoldopam was associated with a lower risk of the need for renal replacement and in-hospital death.⁵¹

SPECIAL CONSIDERATIONS
Hypertension in Pregnancy
Hypertension, although common in the general population, is also a complication in 10% of pregnancies worldwide. Although the etiologies of hypertension are multifactorial, the American College of Obstetricians and Gynecologists has streamlined hypertension during pregnancy to four categories: (1) preeclampsia-eclampsia, (2) chronic hypertension, (3) chronic hypertension with superimposed preeclampsia, and (4) gestational hyper-tension. Of these, preeclampsia is the most commonly seen etiology of hypertension in pregnancy and is most often associated with hypertensive emergency. Preeclampsia typically develops after 20 weeks of gestation and may manifest through the postpartum period. Diagnostic criteria for preeclampsia include elevated blood pressure of 140/90 mm Hg or greater (on two separate occasions) or confirmed persistent blood pressure of 160/110 mm Hg or greater, and concomitant proteinuria or any of thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, or cerebral/visual symptoms (Table 37.3). Hypertensive urgency in the pregnant patient is defined as an SBP of 180 mm Hg or greater and/or a DBP of 120 mm Hg or greater without progressive end-organ damage. Hypertensive emergency in the pregnant patient is defined as persistent (15 minutes or more) hypertension (SBP of 160 mm Hg or greater and/or DBP of 110 mm Hg or greater) in a pregnant or postpartum patient with preeclampsia or eclampsia. Blood pressure criteria for hypertensive emergency are set at lower levels because peripartum patients may develop complications of hypertensive crisis, such as myocardial infarction, stroke, hypertensive encephalopathy, and pulmonary edema, at lower levels of hypertension compared with the general population.

For pregnant patients presenting with hypertensive crisis, initial clinical goals of patient stabilization and prevention of end-organ damage remain at the forefront, but in addition, preservation of adequate uteroplacental perfusion must be considered. For patients with hypertensive urgency, blood pressure should be lowered slowly over 24–48 hours, and oral antihypertensive agents are typically used. For patients with hypertensive emergency, immediate blood pressure...
intervention should be made, with goals of reducing MAP by 15%–25% and/or a goal SBP range of 140–150 mm Hg and a DBP range of 90–100 mm Hg. In addition to antihypertensive medications, other interventions may be considered such as administration of magnesium for associated eclampsia, support of end-organ dysfunction, and consideration of fetal delivery. A recent Cochrane review showed no preferred agent for the treatment of hypertensive emergency in pregnancy, though—as with all hypertensive crisis treatment options—intravenous agents that are short acting and titratable are preferred.55

<tr>
<td>Intracranial hemorrhage</td>
<td>SBP &gt; 200 mm Hg or DBP &gt; 150 mm Hg OR SBP &gt; 150 mm Hg or MAP &gt; 130 mm Hg with possibility of increased ICP</td>
<td>Guideline recommendation: “Aggressive reduction of blood pressure with frequent monitoring” and/or Goal SBP &lt; 180 mm Hg</td>
<td>Common first-line intermittent therapy: labetalol, hydralazine. Common first-line CI: nicardipine, clevidipine, labetalol</td>
</tr>
<tr>
<td>Ischemic stroke</td>
<td>SBP &gt; 220 mm Hg or DBP &gt; 120 mm Hg.</td>
<td>Reduction in SBP recommended. Initial lowering of SBP by 15% and follow neurologic status</td>
<td>In patients post-thrombolysis with tPA: Goal SBP &lt; 180 mm Hg &amp; DBP &lt; 120 mm Hg. Labetalol (bolus &amp; CI) and nicardipine typical first-line agents for BP lowering.</td>
</tr>
</tbody>
</table>
Commonly used agents include intravenous hydralazine and labetalol as first-line options with safety evidence established in pregnant patients, though limited comparative data exist. Nicardipine may also be used in pregnant patients, with a recent meta-analysis showing increased success of blood pressure control in patients receiving nicardipine compared with labetalol, with a more favorable fetal adverse event profile warranting further investigation. Sodium nitroprusside may be considered as a last-line agent, though accumulation of cyanide or thiocyanate limits its use. Enalaprilat should be avoided because ACEI agents and angiotensin receptor blocking agents are contraindicated in the second and third trimesters of pregnancy. Esmolol should be avoided unless necessary by another compelling indication (such as aortic dissection) because it crosses the placenta and is associated with fetal bradycardia and persistent β-blockade (Figure 37.1).

**Neurologic Injury**
Intracerebral Hemorrhage

Elevated blood pressure is commonly seen in patients with hemorrhagic stroke. The newly published 2015 guidelines for the management of spontaneous intracerebral hemorrhage (ICH) from the American Heart Association/American Stroke Association (AHA/ASA) contain updated recommendations for blood pressure management. For patients with ICH having an SBP between 150 and 220 mm Hg, the guidelines now state that lowering the SBP to 140 mm Hg is safe and can be effective for improving functional outcome, provided there are no contraindications to acute blood pressure treatment. This is a stronger recommendation for an SBP goal of 140 mm Hg in ICU patients than the previous 2010 guideline. For patients with an SBP greater than 220 mm Hg, the guidelines state that it may be reasonable to consider aggressive reduction in blood pressure, but they do not provide a specific target or goal at this time (Table 37.3). Much of this is based on data from the Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT1) and the Antihypertensive Treatment in Acute Cerebral Hemorrhage (ATACH) and the second Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT2) investigations. The phase III ATACH II trial is currently enrolling patients to investigate early intensive compared with standard blood pressure control in patients with spontaneous ICH, which may help further guide care in these patients. One area where specific blood pressure recommendations remain unclear from a guideline perspective is in patients with oral anticoagulant–associated ICH. Patients with oral anticoagulant–associated ICH present with challenges similar to those in patients with spontaneous ICH, but they also carry consideration for urgent reversal of anticoagulation. Oral anticoagulant therapy not only increases the risk of ICH in general but is also associated with an increased rate of hematoma enlargement. A recent review of a large cohort of patients with oral anticoagulant–associated ICH shows decreased hematoma expansion in patients with an SBP less than 160 mm Hg within 4 hours after hospital admission. There is no evidence assessing intensive treatment with an SBP goal of less than 140 mm Hg in the setting of
oral anticoagulant–associated ICH, though this may be an appropriate goal for this population.

Currently, no specific medication agents are recommended as first-line agents from guideline recommendations (Figure 37.2). It is stated, however, that for patients with an SBP greater than 220 mm Hg, aggressive management of blood pressure reduction with a continuous intravenous infusion should be considered. Despite no guideline-endorsed agents of choice, some data suggest certain optimal agents for blood pressure management in ICH. Typical first-line agents for intermittent administration include labetalol and hydralazine, with calcium channel antagonists, sodium nitroprusside, and labetalol as continuous infusion when required. Many direct comparisons between agents are small and retrospective and suggest overall similar lowering of MAP and clinical outcomes in patients with labetalol versus nicardipine, with differences dependent on route of administration (i.e., intravenous vs. intermittent bolus) meriting further investigation. The ongoing ATACH II trial will hopefully shed more light on characterizing nicardipine use in this population. Open-label, single-agent investigations using nicardipine and clevidipine show efficacy in maintaining blood pressure goals in patients with ICH and tolerable safety profiles. Sodium nitroprusside has fallen out of favor because of its unfavorable adverse effect profile and the availability of newer agents, and, according to one large database review, it may be associated with higher mortality than nicardipine in patients with ICH.
Figure 37.1  Management of hypertensive crisis in pregnancy.

BP = blood pressure; HTN = hypertension.
Ischemic Stroke
As in hemorrhagic stroke, elevated blood pressure may be observed in patients with ischemic stroke, which is often higher in those with preexisting hypertension, and management of extreme hypertension must be balanced with maintaining cerebral perfusion to vulnerable tissue. Although an absolute blood pressure target in the acute phase is as yet undefined, elevated blood pressure in patients with ischemic stroke has been associated with poorer outcomes. Observational data show a U-shaped relationship between blood pressure parameters and outcome measures, such as early neurologic deterioration, poor neurologic outcome, and mortality, with poor outcomes associated with extremes of both hypotension (120/70 mm Hg or less) and hypertension (200/110 mm Hg or greater). The AHA/ASA Guidelines for the Early Management of Patients with Acute Ischemic Stroke
recommend limited blood pressure intervention in the initial 24-hour period after ischemic stroke unless blood pressure is 220/120 mm Hg or greater or there is a concomitant indication for intervention such as myocardial infarction or aortic dissection. Although an absolute numerical target for blood pressure management of hypertension in acute ischemic stroke has yet to be defined, guideline-based treatment calls for an SBP reduction by 15% in concert with clinician judgment in patients with hypertension in early acute ischemic stroke. The more recent China Antihypertensive Trial in Acute Ischemic Stroke (CATIS) found that acute blood pressure lowering by 10%-25% in patients with non-recombinant tissue plasminogen activator with SBP 140-220 mm Hg during the first 24 hours of acute ischemic stroke may be safe; however, further investigation is needed before early intervention for patients with a blood pressure of 220/110 mm Hg or less becomes part of routine management in the early phase of ischemic stroke (Table 37.3).

One subset of patients with ischemic stroke with clearly defined blood pressure goals consists of patients eligible for antifibrinolytic therapy with recombinant tissue plasminogen activator. Retrospective evaluations of recombinant tissue plasminogen activator in ischemic stroke use suggest that any protocol deviations with thrombolytic use, including blood pressure control, as well as hyperglycemia and baseline coagulation, are associated with an increased incidence of hemorrhage. Blood pressure control in patients receiving recombinant tissue plasminogen activator should be monitored closely to ensure mitigation not only of hemorrhagic events, but also as a component of overall progress toward optimal outcomes. For patients eligible for recombinant tissue plasminogen activator therapy, blood pressure should be maintained greater than 185/110 mm Hg before administration using medical therapy (labetalol, nicardipine) as needed. After administration of recombinant tissue plasminogen activator, blood pressure should be monitored frequently to maintain a goal of 180/105 mm Hg or greater for 24 hours.

Although recommendations can be made for blood pressure thresholds for treatment of extreme hypertension in ischemic stroke
and management of post–recombinant tissue plasminogen activator administration, evidence-based data recommending the specific agents of choice for initial management of hypertension are limited and littered with conflicting findings.\textsuperscript{66,80,81} The BEST (Beta-Blocker Evaluation in Survival Trial) study found no benefit to administering atenolol or propranolol within 48 hours of ischemic stroke; however, labetalol is often used as a first-choice agent for treatment of hypertension in the ischemic stroke population.\textsuperscript{65,82} In INWEST (Intravenous Nimodipine West European Stroke Trial), subjects receiving intravenous nimodipine had poorer outcomes, though whether this was related to specific properties of nimodipine itself or the pronounced effect seen in DBP is unclear.\textsuperscript{80} Retrospective evaluations of the use of continuous infusion nicardipine, another calcium channel antagonist, support its use as an alternative to other antihypertensive agents such as labetalol without evidence of drug class–mediated deleterious effects, though prospective data in ischemic stroke are needed. The pharmacodynamic profile of the only intravenous ACEI, enalaprilat, limits the use of this class of agents in acute hypertension in ischemic stroke.\textsuperscript{73,83} Although no specific agents are specified in the AHA/ASA Guidelines for the Early Management of Patients with Acute Ischemic Stroke, a general approach to management of hypertension is described, based largely on clinical opinion and agents used in recombinant tissue plasminogen activator investigations. Labetalol is recommended as the first-line agent of choice for intermittent bolus administration together with nicardipine for continuous infusion. Although not specified in the 2013 guidelines, clevidipine may be considered according to institutional availability and preference. The guidelines do mention consideration of other agents such as hydralazine and enalaprilat when clinically appropriate and consideration of sodium nitroprusside in patients with uncontrolled hypertension with the agents previously mentioned or a DBP greater than 140 mm Hg (Figure 37.3).\textsuperscript{72}
Subarachnoid Hemorrhage
Patients presenting with aneurysmal subarachnoid hemorrhage (aSAH) may have a variety of blood pressure management needs throughout their treatment process because altered autoregulation, concern for rebleeding events, and delayed neurologic defects are just a few processes in aSAH that may be affected by blood pressure alterations. Rebleeding in aneurysm rupture is associated with increased mortality.
and morbidity, with peak rebleeding seen within the first 24 hours after aneurysm rupture, often within the first 6–12 hours.\textsuperscript{84,85} Early surgical or endovascular intervention has helped attenuate the incidence of in-hospital rebleeding in aSAH; however, rebleeding may occur, and due consideration should be given to management of hypertension before aneurysm obliteration. Systolic blood pressures greater than 160 mm Hg and MAPs less than 70 mm Hg or greater than 130 mm Hg have been associated with rebleeding and poor outcome in aSAH (Table 37.3).\textsuperscript{86,87} The AHA/ASA Guidelines for the Management of Aneurysmal Subarachnoid Hemorrhage recommend that acute hypertension be controlled, particularly before definitive aneurysmal intervention, with a recommendation that “a decrease in systolic blood pressure to less than 160 mm Hg is reasonable.”\textsuperscript{88} There are no specified blood pressure parameter recommendations post-intervention within the guideline, but close attention should be paid to blood pressure monitoring after intervention.

Although there is some evidence specific to the aSAH population regarding antihypertensive selection, the AHA/ASA guidelines make no specific endorsements for particular agents. One retrospective investigation shows efficiency in achieving blood pressure goals with improved time within goal MAP, decreased needs for additional antihypertensive agents, and number of treatment failures with continuous infusion nicardipine similar to that with bolus-dose labetalol.\textsuperscript{89} It has also been shown that continuous infusion labetalol versus continuous infusion nicardipine has similar maintenance of blood pressure goals in patients with aSAH and ICH, though with a faster time to goal MAP with nicardipine.\textsuperscript{67} A prospective evaluation of nicardipine and sodium nitroprusside infusions for acute blood pressure control has been done in patients with aSAH and ICH. Overall blood pressure control was similar between both treatment groups, with similar time spent within target blood pressure range but with overall fewer adjustments to infusion doses and requirements of additional as-needed medication in patients receiving nicardipine.\textsuperscript{90} An open-label pilot study of five patients also suggests that clevidipine can successfully be used for acute blood pressure management in aSAH,
though larger investigations are warranted.\textsuperscript{91} Although firm recommendations regarding antihypertensive agent selection cannot be made at this time, institutional blood pressure goals and medication availability should be considered. Given the risk of early rebleeding and the recommended SBP goals of 160 mm Hg or less, continuous infusion preparations may yield less blood pressure variability, which may correlate with improved overall patient outcomes, though there is scant evidence at best to support this at this time (Figure 37.4).

**Postoperative Hypertension**

Hypertension is a common occurrence in postoperative patients, and though commonly seen, no specific criteria exist for diagnosis. Acute postoperative hypertension (APH) typically has an early onset, within 2 hours after surgery, and typically abates within 6 hours or less, though may persist beyond that period. Factors predisposing patients include preoperative conditions such as hypertension, diabetes mellitus, and renal disease; postoperative factors such as pain, anxiety, and emergence from anesthesia; and intraoperative factors such as type of surgery performed, duration of procedure, and anesthetic agents used. Although many factors play a role in APH, preoperative hypertension is highly associated with the development of postoperative hypertension and should be considered in the perioperative workup.\textsuperscript{92–94} Although several risk factors exist for APH, activation of the sympathetic nervous system with elevation of plasma catecholamines appears to be higher in patients with APH. It does not appear that the RAAS plays a significant role in the development of postoperative hypertension, at least in the cardiac surgery population, though data suggest that the RAAS does play a role in other patient populations.\textsuperscript{95–97} Although the full pathophysiology of APH has yet to be fully described, interventions should be made to prevent serious sequelae such as hemorrhagic stroke or cerebral ischemia, cardiovascular complications, pulmonary edema, or complications related to surgical site and bleeding.
At this time, there is a lack of consensus regarding both the definition of APH and the optimal treatment goals for patients with non-cardiac surgery. Definitions for APH in non-cardiac surgery as defined by clinical investigations range from blood pressure measurements of SBP of 180–200 mm Hg or greater (140 mm Hg or greater in neurosurgical postoperative investigations), DBP of 110 mm Hg or greater (95 mm Hg or greater in neurosurgical postoperative investigations), MAP of 20% or greater of baseline value, or some combination thereof (Table 37.3).\textsuperscript{98–100} Treatment interventions should include mitigation of causes of APH such as hypothermia and shivering, optimization of ventilatory parameters, adequate analgesia and sedation as needed, management of volume status, and other reversible causes. Once these are optimized, antihypertensive medication can be considered for treatment of APH with goal blood
pressure lowering at surgeon/anesthesiologist discretion in non-cardiac surgery. Because most APH is transient, short-acting agents, such as labetalol, as well as agents that are easily titratable, such as nicardipine, clevidipine, and sodium nitroprusside, can be considered. Agents with less uniform responses to therapy or with long durations of action, such as hydralazine and enalaprilat, are not routinely recommended for use in APH and should be used with caution, if at all.

A few key studies have compared various intravenous agents for the management of APH. One multicenter, prospective, randomized study that sought to compare the safety and efficacy of nicardipine with that of sodium nitroprusside in both cardiac and non-cardiac surgical patients found that both agents were equally effective. Patients receiving nicardipine appeared to have more rapid control of APH. Furthermore, the total number of dose titrations to achieve target blood pressure was fewer in the group receiving nicardipine. No difference occurred in rates of adverse events. In a randomized, double-blind, placebo-controlled trial completed by investigators in the ESCAPE-2 (Endovascular Treatment for Small Core and Proximal Occlusion Ischemic Stroke) trial, researchers sought to determine the safety and efficacy of clevidipine in treating APH after cardiac surgery. Clevidipine was associated with lower rates of treatment failure than placebo with no difference of adverse events.

The ECLIPSE (Evaluation of Clevidipine in the Perioperative Treatment of Hypertension Assessing Safety Events) trial compared the efficacy of clevidipine with that of sodium nitroprusside, nitroglycerin, and nicardipine for the management of acute hypertension post–cardiac surgery. This study was a multicenter, prospective, open-label, randomized, parallel comparison study. The primary end point of this trial was a composite end point of safety assessed by the incidence of all-cause mortality, stroke, myocardial infarction, and renal dysfunction. Mortality was significantly higher in the treatment group receiving sodium nitroprusside versus clevidipine. Clevidipine was also more effective than nitroglycerin or sodium nitroprusside in maintaining blood pressure within target ranges. There was no difference in efficacy between clevidipine and nicardipine unless the target blood
Pheochromocytoma
Pheochromocytomas are catecholamine-producing tumors arising from the chromaffin cells of the adrenal gland, though 10%–15% of tumors may be extra-adrenal. Although the prevalence in patients with hypertension is only 0.2%–0.4%, pheochromocytoma is often on the differential diagnosis for patients with acute, otherwise unexplained hypertensive crisis. Of note, patients with pheochromocytoma may also be normotensive or only moderately hypertensive (Table 37.3). About one-fourth of pheochromocytomas are hereditary, and typical symptoms such as headache, sweating, and palpitation are caused by tumor-secreted catecholamines. In most cases, catecholamines are released intermittently, typically both epinephrine and norepinephrine with a predominance of norepinephrine. For patients with pheochromocytoma with hypertensive crisis, management with an α-receptor antagonist such as phentolamine is the recommended initial treatment. After initiation of α-receptor blockade, β-receptor antagonists, such as esmolol, may be required for additional mediation of epinephrine-mediated effects or tachycardia induced by α-receptor antagonism. Surgical resection is often used for definitive treatment of patients with pheochromocytoma, though around 10% of cases are malignant, requiring additional interventions with chemotherapy and radiation. Preoperative initiation of α-blockade with phenoxybenzamine is recommended with the addition of β-receptor antagonists as needed. There is some evidence using calcium channel antagonists in the preoperative period, but data regarding use in pheochromocytoma-induced hypertensive crisis are scarce. Clinical judgment on a case-by-case basis is recommended in patients with pheochromocytoma with hypertensive crisis not responding adequately to α- and β-receptor antagonism.103,104

Aortic Dissection
Aortic dissection, although present in only 2% of patients presenting
with hypertensive crisis, is rapidly fatal and can be considered a surgical emergency. Elevated blood pressures in conjunction with atherosclerosis within the aorta can result in tears within the intimal layer of the blood vessel. These tears permit the development of a false lumen within the wall of the aorta. As blood is ejected from the left ventricle and into the aorta, the resulting high pulsatile pressure separates the aortic wall into two layers. Therefore, clinically, patients with dissection present with symptoms of retrosternal or interscapular chest pain that radiates down the back. Dissection can result in impeded blood flow to branches of blood vessels from the aorta, leading to end-organ ischemia. Diagnosis is usually confirmed by transesophageal echocardiography, CT (computed tomography), or MRI (magnetic resonance imaging).

There are three major classification systems for aortic dissection (Table 37.4). The Stanford system is the most classically used by surgeons because it is a simple guide to determine whether the patient is a surgical emergency. A type A dissection according to the Stanford system would likely be considered a surgical emergency. These patients may present with symptoms associated with malperfusion of the brain and coronary arteries. Conversely, type B dissections may present with symptoms of malperfusion of the spinal cord, liver, small intestines, kidneys, or lower extremities. Several different patient-specific features have been seen among patients presenting with dissection. Disease states such as hypertension, hyperlipidemia, diabetes, and Marfan syndrome have been associated with increasing risk. Furthermore, pregnancy, cocaine abuse, a history of cardiac surgery, or the presence of a bicuspid aortic valve may also be associated with dissection.

To avoid propagation of intimal dissection, patients presenting with aortic dissection require immediate intravenous antihypertensive treatment as soon dissection is suspected. An exception to this would be a subset of patients who may present as hypotensive as a result of their dissection. Progression of the dissection depends on the degree of blood pressure elevation as well as the velocity of left ventricular ejection. For this reason, therapeutic interventions aimed at both heart
rate and blood pressure are used for these cases. Emergency intervention usually involves rapid intravenous administration of β-blocking agents such as esmolol in an attempt to reduce heart rate to less than 60 beats/minute.\textsuperscript{43} Vasodilating agents such as nicardipine or sodium nitroprusside may be added to β-blocking agents to achieve an SBP less than 120 mm Hg. The DBP should be reduced by 10%–15%, or at least to less than 110 mm Hg. These interventions and targets are ideally obtained within 20 minutes (ideally within 5–10 minutes) of presentation to the health care setting.\textsuperscript{106} Although esmolol is not FDA approved for hypertensive crisis with aortic dissection, it has been used to treat hypertension associated with acute aortic dissection (Figure 37.6). In sequence of administration, β-blocking agent administration should precede the initiation of any antihypertensive agent that may cause reflexive tachycardia or position inotropy to avoid exacerbating the dissection. These hemodynamic end points should be maintained as long as the patient remains symptomatically stable or until the patient can be taken to the operating room for more definitive management of the dissection.\textsuperscript{107}

• Class 2: intramural hematoma or hemorrhage
• Class 3: subtle dissection without hematoma
• Class 4: atherosclerotic penetrating ulcer
• Class 5: iatrogenic or traumatic dissection

---

**Acute Coronary Syndromes**

Hypertensive crisis can negatively affect both the structure and the function of the left ventricle as well as coronary circulation. The RAAS is activated, resulting in systemic vasoconstriction and increased myocardial oxygen demand and subsequent left ventricular hypertrophy. Coronary blood flow is negatively affected by both this hypertrophy and the endothelial destruction within the capillaries as a result of acute rises in blood pressure. Therefore, patients with hypertensive crisis can present with acute coronary syndromes (Table 37.3).

In patients with coronary artery disease presenting with an acute coronary syndrome, the theoretical “coronary steal” (i.e., redistribution of oxygenated blood away from non-vasodilating areas of ischemia toward nonischemic myocardium with dilated coronary arteries) results in reduced coronary perfusion pressure to further exacerbate and potentiate injury. A study by Mann and colleagues examined the effects of sodium nitroprusside on regional myocardial blood flow in patients with coronary artery disease. These investigators found that sodium nitroprusside significantly reduced regional myocardial specific blood flow and increased coronary artery vascular resistance. This effect was seen regardless of the presence of collateralization. Therefore, sodium nitroprusside should not routinely be administered to
patients with hypertensive emergency in the setting of acute coronary syndromes because it has been associated with increased mortality. This was especially prominent when it was administered within 9 hours of onset of chest pain in patients with acute coronary syndrome and elevated left ventricular filling pressure.

Nitroglycerin decreases preload and myocardial oxygen consumption by decreasing left ventricular end-diastolic volume and myocardial wall tension, making it the preferred agent in the setting of hypertensive crisis complicated by myocardial ischemia. However, before the administration of any nitrate medication, the medical team should determine whether the patient has been taking a phosphodiesterase type 5 (PDE-5) inhibitor because the combination can cause profound hypotension for up to 48 hours after the last dose of a PDE-5 inhibitor. In one study, standing SBP fell below 85 mm Hg in
more patients receiving tadalafil than in placebo (p<0.05), with no difference in the response to sublingual nitroglycerin. Within 48 hours after the last dose of a PDE-5 inhibitor, ischemic chest pain can be treated with β-blockers, calcium channel blockers, morphine, oxygen, and aspirin while avoiding nitrates.110

Intravenous β-blocking agents are also an option for these patients. A meta-analysis of patients receiving β-blockers post–acute coronary syndrome found a 14% risk reduction in mortality through 7 days and a 23% reduction in long-term mortality. In-hospital β-blocker administration can reduce myocardial infarct size and rates of mortality, postinfarction ischemia, and nonfatal acute myocardial infarction.111 These agents may also be beneficial for non–ST-segment elevation myocardial infarction. The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) study randomized patients to receive early treatment with intravenous metoprolol or placebo after acute myocardial infarction. Investigators found that although early intravenous metoprolol in this setting reduced the risks of reinfarction and ventricular fibrillation, it increased the risk of cardiogenic shock.112 This finding was especially observed within the 24 hours after admission. Although oral β-blocker therapy is still recommended, the authors cautioned against initiating intravenous β-blocker therapy. Rather, the authors purported that intravenous β-blockage should only be initiated after the post–myocardial infarction hemodynamic status has stabilized.111 Contraindications to β-blockers include moderate to severe left ventricular dysfunction with pulmonary edema, hypotension, second- or third-degree heart block, bradycardia, and reactive airways disease.48

Enalaprilat would appear to be an ideal agent in managing hypertensive crisis when a patient presents with acute coronary syndrome, given the activation of RAAS that is seen. However, the Cooperative New Scandinavian Enalapril Survival Study II (CONSENSUS II) showed a trend toward increased mortality when enalaprilat was administered within 24 hours of acute myocardial infarction. Of note, this observation may have occurred because of hypotension after drug administration. However, it may be considered a
favorable option in patients with hypertensive emergency in the setting of left ventricular failure, given that ACEI agents are a key intervention in the management of heart failure (Figure 37.7).\textsuperscript{113}

**Cocaine Intoxication**

Cocaine is an illicit drug derived from the leaves of the coca plant (Erythroxylum coca) and is predominantly found in the Andes mountain range of South America. Historically, natives of this region would chew the leaves of the coca plant to relieve fatigue. Cocaine was extracted and used for medicinal purposes as an ophthalmic anesthetic during eye surgery in the 1880s. Subsequently, cocaine was widely used in the United States. It was an ingredient in the recipe for the original Coca-Cola. Legislation to make cocaine and illegal substance dates back to the early 20th century; however, cocaine remains a common drug of abuse.

Cocaine has three distinct mechanisms of action. It is an indirect sympathomimetic that blocks the presynaptic reuptake of biogenic amines at adrenergic receptors. This mechanism has been seen in neurons containing serotonin, dopamine, norepinephrine, and epinephrine. Overall, this results in vasoconstriction in both cardiac and peripheral vasculature.\textsuperscript{114,115} This sympathomimetic activity is also seen in its stimulation of $\alpha$- and $\beta$-adrenergic receptors, resulting in increased myocardial demand and impaired perfusion. The euphoric properties of cocaine are a result of inhibition of serotonin reuptake in the central nervous system. Cocaine is also a sodium channel blocker, resulting in slowed nerve conduction and an anesthetic effect. In severe overdose, cardiac sodium channel blockade manifests as prolongation of the QRS complex on electrocardiogram and clinically as negative inotropy. Finally, cocaine increases the concentration of the excitatory amino acids glutamate and aspartate in the central nervous system, particularly in the nucleus accumbens.

Symptoms of acute ingestion or overdose vary by organ system affected. With the cardiovascular system, arterial vasoconstriction is seen in addition to a prothrombotic state.\textsuperscript{114,115} It can cause tachycardia, hypertension, increased myocardial oxygen demand, and
increased vascular shearing forces. Cocaine causes dose-dependent coronary vasoconstriction and is associated with cardiac ischemia.\textsuperscript{116--118} The negative inotropic effects shown by high doses of cocaine may cause acute depression of left ventricular function and acute decompensated heart failure. Cocaine can also cause supraventricular and ventricular dysrhythmias through several mechanisms. Aortic dissection and rupture rarely occur as a result of acute intoxication.\textsuperscript{119,120} Furthermore, coronary artery aneurysms are relatively common in these patients and may be another potential cause of myocardial infarction.\textsuperscript{121--123}

When clinically evaluating a patient presenting with suspected cocaine intoxication or overdose, capillary blood glucose, acetaminophen concentrations, and salicylate concentrations should be ascertained to rule out hypoglycemia and possible common co-ingestions. The patient’s core temperature should be evaluated, and concomitant hyperthermia should be treated, if needed. Cocaine is rapidly metabolized and detectable in blood and urine only briefly after use. Benzoylecgonine is the major metabolite in cocaine that can be detected in the urine for several days after intermittent use and up to 10 days after heavy use. Benzoylecgonine can also be found in the blood, saliva, hair, and meconium of patients with suspected overdose. Because patients may have packed their body cavities with cocaine in an attempt to transport the drug, radiographs may be warranted to ensure their removal to avoid possible continued absorption. Patients with overdose who experience chest pain should prompt electrocardiogram measurements to evaluate for any conduction system abnormalities. Serum biomarkers to detect the presence of circulating troponin, myoglobin, creatine kinase (CK), or CK-MB may be warranted in the setting of chest pain and abnormal electrocardiogram.

Patients with cocaine-related unstable angina, non-ST-segment elevation myocardial infarction, or ST-segment elevation myocardial infarction are treated in a manner similar to other patients with acute coronary syndrome. The most important exception to this is the administration of medications with unopposed $\alpha$-blockade.
Administration of such agents can cause coronary artery vasoconstriction, systemic hypertension, and increased severity and duration of cocaine toxicity. Furthermore, there are theoretical concerns of coronary artery vasoconstriction and systemic hypertension, which can result from unopposed α-adrenergic stimulation. In addition, mortality rates in patients with cocaine-associated myocardial infarction are low; thus, the usual benefit from β-blockers after myocardial infarction may be lost.

**Figure 37.7** Management of hypertensive crisis associated with acute coronary syndromes.

In addition to treatment with antihypertensive agents, patients who may have recently used cocaine may have significant psychomotor agitation, which may contribute to their hypertensive crisis. Adequate sedation with benzodiazepines may be needed in addition to the aforementioned management strategies (Figure 37.8).

**Acute Pulmonary Embolism**
Almost 50% of patients with an acute pulmonary embolism are hypertensive as a result of accompanying dyspnea, anxiety, or chest pain. Administration of supplemental oxygen, afterload reduction, preload reduction, and diuresis are the mainstay therapeutic interventions in the management of hypertensive crisis caused by acute pulmonary embolism. Blood pressure reduction decreases myocardial oxygen demand and may also enhance cardiac output. Nitroglycerin and sodium nitroprusside are the intravenous antihypertensives most commonly used in this setting. In one single-group, nonrandomized, open-label, standard therapy controlled study, high-dose nitroglycerin
infusions were used to aggressively lower blood pressure (SBP of 160 mm Hg or greater or MAP of 120 mm Hg or greater) in patients with acute pulmonary embolism with acute decompensated heart failure refractory to initial antihypertensive therapy (Table 37.3). Study investigators used bolus doses of intravenous nitroglycerin (2 mg intravenously every 3 minutes up to 10 doses) and adjusted dosing to desired symptomatic response. High-dose nitroglycerin administration resulted in fewer ICU admissions, fewer endotracheal intubations, and fewer troponin-level elevations compared with standard therapy. Only one patient in the intervention group developed symptomatic hypotension compared with none in the standard treatment arm. Fewer patients in the high-dose nitroglycerin treatment arm had troponin elevations or biomarker evidence of myocardial infarction. Overall, rapid blood pressure management in patients with acute severe pulmonary congestion as a result of their acute pulmonary embolism may result in the avoidance of endotracheal intubation.

Chapter 38  Medication Withdrawal in the Intensive Care Unit

Colgan T. Sloan, Pharm.D., BCPS; Robert French, M.D., MPH; Nicholas B. Hurst, M.D., M.S.; Stephen R. Karpen, Pharm.D.; and Mazda Shirazi, M.D., Ph.D.

LEARNING OBJECTIVES
1. Identify medications that, if discontinued, may complicate the care of patients in the intensive care unit (ICU).
2. Discuss the diagnosis of medication withdrawal in ICU patients.
3. Review treatment strategies for ICU patients thought to have medication withdrawal.

ABBREVIATIONS IN THIS CHAPTER

- GABA: γ-Amino butyric acid
- ICU: Intensive care unit
- NRT: Nicotine replacement therapy
- SNRI: Serotonin and norepinephrine reuptake inhibitor
- SSRI: Selective serotonin reuptake inhibitor
INTRODUCTION

Medication withdrawal is a potentially serious complication in all patients taking chronic medications; some medication classes pose a greater risk of withdrawal. We identified popular medications with clinically relevant withdrawal syndromes. It must be stressed that the evidence base for many of the recommendations in this chapter is of moderate to low quality. Many of the recommendations from this chapter are based on limited evidence and expert opinion; we implore readers to apply these recommendations judiciously to patient care. The many contributing factors to the paucity of high-quality evidence in this area include underrecognition by clinicians, methodological limitations (e.g., small sample size, nonrandomized, retrospective), and ethical concerns with treating potentially life-threatening withdrawal syndromes with substandard comparators. The ICU team should diligently identify medications with a withdrawal concern and anticipate how to address these, being wary not to overlook iatrogenic causes of medication withdrawal. In reviewing medications that may have pertinent withdrawal symptoms, we hope to raise awareness about this potentially overlooked aspect of patient care within the intensive care unit (ICU).

BACLOFEN WITHDRAWAL

Background

Baclofen (4-amino-3(p-chlorophenyl)butyric acid) is structurally similar to the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Baclofen is an agonist at the GABA-B receptors located in the dorsal horns of the spinal cord and elsewhere in the central nervous system (CNS) (see Figure 38.1). Although its mechanism of action in the treatment of muscular spasticity is not entirely known, baclofen is believed to suppress the release of excitatory neurotransmitters involved in monosynaptic and polysynaptic stretch reflexes, resulting in reduced muscle tone and vasospasm.1

Baclofen is used orally or intrathecally in the treatment of chronic
muscular spasticity caused by neurologic injury and neuromuscular disorders such as spinal cord injury, multiple sclerosis cerebral palsy, and traumatic brain injury. Oral baclofen has been used in the treatment of alcohol abuse disorder and other addiction disorders; it too is abused.

Intrathecal baclofen is administered using a programmable metallic infusion pump that is surgically implanted, typically in the lower abdomen. The pump stores and releases the programmed amount of baclofen through a flexible catheter into the intrathecal space. Long-term administration causes down-regulation of GABA-B receptors. Interrupting intrathecal baclofen administration because of problems with the pump or the catheter can lead to an acute life-threatening withdrawal state that is characterized by delirium, autonomic instability, hyperthermia, and muscular spasticity. Patients who have a baclofen pump are therefore technology-dependent.

**Diagnosis**

Baclofen withdrawal is a clinical diagnosis. Neuropsychiatric symptoms include auditory, visual, and tactile hallucinations; delusions; confusion; agitation; disorientation; fluctuation of consciousness; insomnia; anxiety; depersonalization; and formal thought disorder. Other signs and symptoms include rebound spasticity, autonomic instability, hyperthermia, and pruritus. Withdrawal should be considered when suggestive symptoms occur in a patient who is receiving chronic oral baclofen therapy, abuses oral baclofen, has an intrathecal baclofen pump, or, in the absence of a reliable medication history, has a history of or examination findings suggestive of chronic muscle spasticity. In a review of published case reports, the latency until onset of withdrawal symptoms was 1–4 days after the cessation of oral baclofen and 12–24 hours after the cessation of intrathecal baclofen. A differential diagnosis is presented in Table 38.1.

**Management**

Definitive management of acute baclofen withdrawal involves resuming
baclofen therapy. Management of withdrawal from intrathecal baclofen is therefore more complicated than management of withdrawal from oral baclofen.

![Baclofen and γ-amino butyric acid](https://commons.wikimedia.org/wiki/File:Baclofen.svg;https://commons.wikimedia.org/wiki/File:Gamma-Aminobutters%C3%A4ure_-_gamma-aminobutyric_acid.svg)

**Figure 38.1** Baclofen (top); γ-amino butyric acid (bottom).

The pump should be interrogated by a physician familiar with intrathecal infusion pumps. Pump-related problems include programming errors, battery exhaustion, and low residual volume. Forty percent of withdrawal states are the result of catheter-related problems; therefore, the integrity of the catheter should be investigated by abdominal radiograph or catheterogram. Catheter-related problems include migration, kinking, breakage, and leaks where the catheter meets the pump.  

A variety of medications, and combinations of medications, have been used to control symptoms during the interval between presentation and restoration of intrathecal baclofen delivery. Evidence
supporting any specific therapeutic action is lacking. Enteral baclofen is often used; however, it is generally considered ineffective because adequate CNS concentrations cannot be attained. Propofol and benzodiazepines are both GABA-A receptor agonists and therefore potentially bypass the down-regulated CNS GABA-B receptors. Baclofen has been used to treat withdrawal in a patient with chronic use of γ-hydroxybutyrate (GHB). Sodium oxybate (Xyrem), a U.S. Food and Drug Administration (FDA)-approved medication with the same chemical structure as GHB, as a treatment for baclofen withdrawal has not been reported. Given the FDA’s REMS (Risk Evaluation and Mitigation Strategies) in place for sodium oxybate, clinicians will not likely have access to sodium oxybate. Cyproheptadine has been used to control serotonergic findings.

Cases in which intrathecal baclofen is interrupted because of the removal of an infected pump are particularly problematic because intrathecal baclofen cannot readily be resumed. Such cases have resulted in withdrawal states lasting more than 1 month, only to be resolved once the infection clears and the pump is replaced. In one study, intrathecal baclofen administered using an indwelling lumbar drain catheter in conjunction with a patient-controlled analgesia pump was used to treat acute withdrawal that occurred after the removal of a catheter because of its proximity to an infection site; this patient was ultimately weaned to oral medication. Intrathecal baclofen through a temporary, externalized, intrathecal catheter was used to prevent withdrawal in a case where the pump and catheter were removed because of infection at the site of the pump.

SELECTIVE SEROTONIN/NOREPINEPHRINE REUPTAKE INHIBITOR WITHDRAWAL

Background
Selective serotonin reuptake inhibitors (SSRIs) and serotonin and norepinephrine reuptake inhibitors (SNRIs) are among the most prescribed pharmaceuticals in the United States. Data from the Centers for Disease Control and Prevention in 2011 showed that 1 in 10 Americans reported taking an antidepressant medication. The SSRIs and SNRIs are considered first-line treatment for depression. They work by modulating the neurotransmission of serotonin and norepinephrine, resulting in increased availability of these molecules at the synaptic cleft and thereby affecting mood. The exact mechanism of this effect is unknown.

Case reports describing withdrawal reactions after cessation of these agents began to appear in the medical literature in the 1990s. These reports described a range of symptoms including extrapyramidal effects, shocklike sensations, dizziness, light-headedness, and delirium. Psychological symptoms such as anxiety, irritability, and insomnia were also described. Collectively, these are termed the antidepressant discontinuation syndrome. These symptoms have been described to occur after both abrupt cessation and gradual taper. Onset of symptoms usually occurs a few days after cessation
and can last for weeks.\textsuperscript{28} Agents with longer half-lives or active metabolites tend to be less likely to cause the syndrome.\textsuperscript{29}

More severe reactions have also been reported in the literature. In one case report, a patient developed refractory hypertension after stopping citalopram that resolved on reinitiation.\textsuperscript{30} Another patient had strokelike symptoms and a pill-rolling tremor post-surgically that was attributed to discontinuing milnacipran the night before. After a negative workup, the patient’s milnacipran was reinitiated, and the symptoms resolved.\textsuperscript{31} These cases show the importance of including SSRI/SNRI withdrawal syndrome in the differential of critically ill patients.

**Diagnosis**

Selective serotonin reuptake inhibitor/SNRI discontinuation syndrome is a clinical diagnosis. Diagnostic criteria have been proposed.\textsuperscript{32} These criteria consider both the physical and psychological effects of discontinuation. The diagnosis should be considered in a patient with symptoms of discontinuation syndrome who has been taking an SSRI/SNRI for at least 1 month followed by an abrupt cessation or decrease in dose.

Other etiologies in the critically ill patient should be considered because many of the symptoms are nonspecific. Conversely, in many cases, the symptoms can be attributed to other etiologies such as ICU delirium, sepsis, or stroke, and consideration of SSRI/SNRI discontinuation syndrome may be overlooked (see Table 38.2).

**Management**

General supportive care is indicated for all cases of discontinuation syndrome. Definitive management of SSRI/SNRI discontinuation syndrome involves resuming therapy with the previous agent or another in the same class, unless contraindicated.\textsuperscript{33} The lowest dose that the patient tolerated before the onset of symptoms should be initiated. If the ultimate goal is discontinuation of therapy, a more gradual taper may be tried. Alternatively, switching to another agent with a longer half-life, such as fluoxetine, which has the added benefit of an active
metabolite, may aid in preventing recrudescence of the discontinuation syndrome.\textsuperscript{34}

NICOTINE WITHDRAWAL
Background
Nicotine is the primary component of tobacco and tobacco products responsible for addiction and withdrawal. The underlying pharmacology of its addiction and withdrawal profile is multifactorial and complex. The nicotinic cholinergic receptor (nAChR) is the primary target of nicotine and is found in both the central and peripheral nervous systems. The nAChR is a ligand-gated ion channel structurally composed of five pore-forming subunits. In mammalian neuronal cells, homo- and heteropentameric receptors are composed of $\alpha_2$–$\alpha_{10}$ and $\beta_2$–$\beta_4$ subunits. Ligands of the receptor, such as nicotine, bind at the subunit interfaces, with the relative ion permeability dictated by the specific subunits composing the receptor. The $\alpha_4\beta_2$-receptor subtypes are thought to be primarily responsible for nicotine dependence in people. Agonism of central nAChRs results in the release of dopamine in the mesolimbic area, corpus striatum, frontal cortex, and other areas thought to play a role in drug-induced reward. With chronic stimulation, the amount of nAChRs in the brain is increased. This up-regulation is thought to be because of receptor desensitization. Thus, pharmacologically, nicotine binding may alleviate symptoms of withdrawal.

Diagnosis
It is estimated that 20%–46% of patients admitted to the ICU are smokers and have the potential to have nicotine withdrawal symptoms during their stay. Symptoms generally begin 1–2 days after cessation and peak within the first week. In the outpatient setting, symptoms of nicotine withdrawal classically include irritability, anxiety, dysphoria, restlessness, insomnia, increased appetite, and weight gain. Nicotine withdrawal in the ICU setting has been studied significantly less. In hospitalized but not critical patients, nicotine withdrawal has been reported to include bradycardia, irritability, anxiety, agitation, confusion, and hallucinations. A history of smoking is a risk factor for developing delirium, and there is an increased risk of agitation, an increased risk of self-removal of tubes and catheters, and an increased need for
sedatives, analgesics, neuroleptics, and physical restraints with nicotine abstinence in smokers in the ICU.\textsuperscript{41,42} Management of these symptoms in the ICU patient has not been well studied.

**Management**

The mainstay of therapy for the treatment of nicotine withdrawal in the outpatient setting is nicotine replacement therapy (NRT). Nicotine replacement therapy has been shown to be safe and useful in this population and provides no increased risk of stroke, arrhythmia, angina, myocardial infarction, or death.\textsuperscript{43–45} It remains unclear whether these conclusions hold true in the critical patient. A retrospective case-control review showed an increased risk of mortality in critically ill patients when NRT was used.\textsuperscript{46} An increase in mortality was also seen in critical care cardiovascular smokers receiving NRT compared with smokers not receiving NRT and nonsmokers. We recommend withholding NRT during the ICU stay but continuing NRT after hospital discharge.\textsuperscript{47} A prospective observational study of NRT in the ICU showed no difference in hospital and ICU mortality, hospital length of stay, and 28-day mechanical ventilator– and ICU-free days in active tobacco users receiving NRT compared with those not receiving NRT. Of interest, NRT was associated with more days with a positive CAM-ICU (confusion assessment method for the ICU) score, but a lower median RASS (Richmond Agitation-Sedation Scale) score. Furthermore, higher cumulative doses of opioids and benzodiazepines were required in patients taking NRT, but less dexmedetomidine and haloperidol were required.\textsuperscript{48} Finally, a study of 423 smokers in a mixed medical and surgical ICU assessed the use of transdermal NRT. Therapy in this study consisted of a median dose of 20 mg/day beginning a median of 2.3 days after ICU admission and continuing for a median of 6 days. Use of NRT was more likely to occur in patients previously receiving more than 2 sedatives than in smokers not receiving NRT. Unadjusted survivor length in the ICU was greater in the NRT group, but the hazard ratio for ICU and in-hospital mortality was no different between groups after covariate adjustment.\textsuperscript{49}

Many dosage forms are available for using NRT (gum, nasal spray,
inhalers, tablets, transdermal patches); however, the transdermal route may be preferred in the ICU patient because of ease of use and consistency in nicotine delivery in this population. Nicotine patches deliver 7, 14, or 21 mg over 24 hours. Most studies report use of the 21-mg patch, but several studies do not specify the dose or dosage form used during NRT. Doses of up to 44 mg/day have safely been used. If NRT therapy is tried, we recommend that the 21- or 14-mg/day patch be used; if an accurate smoking history can be obtained, patients smoking more than 10 cigarettes per day should start with the 21-mg/day patch (those smoking 10 or fewer cigarettes per day use the 14-mg/day patch initially). Of note, the patch dosing recommendations are not derived from an ICU population, and individual patient assessment is prudent.

The use of varenicline and bupropion cannot be recommended at this time; these medications have been shown to increase smoking cessation but not to relieve symptoms of nicotine withdrawal. Further studies of their use in the critical care setting are required; ICU clinicians should note that small studies found a decreased risk of mortality in patients with acute subarachnoid hemorrhage but an increased risk of mortality in the cardiothoracic ICU population. Dexmedetomidine and clonidine have been investigated for their role in smoking cessation; however, clinical studies on their safety and efficacy, especially in the critical care population, are lacking.

OPIOID WITHDRAWAL

Background
Opioids are the class of pharmaceuticals that bind to opioid receptors to produce an opium-like effect. Four subtypes of receptors have been identified—µ, κ, δ, and nociceptin/orphanin FQ—which themselves have subtypes. Signal transduction is mediated by G protein–coupled receptors that work through a variety of mechanisms, with the end effect of decreased neuronal transmission. Opioid receptors are found throughout the CNS. The receptors in the locus ceruleus are
thought to mediate the withdrawal syndrome through increased release of norepinephrine when the opioid-induced inhibition is removed.\textsuperscript{58}

The prototypic opioid, morphine, is one of the oldest xenobiotics used as medicinal therapy (see Figure 38.2). Several derivatives and functionally similar compounds now constitute the opioid class of pharmaceuticals. Although some compounds are structurally dissimilar to morphine, as a class, opioids are used primarily in the treatment of acute and chronic pain and are the most commonly used psychoactive substance in the world.\textsuperscript{59} Many formulations exist, together with several routes of administration including oral, intravenous, transdermal, and intranasal.

![Figure 38.2 Morphine](https://commons.wikimedia.org/wiki/File:Morphin_-Morphine.svg)

**Figure 38.2** Morphine.

**Diagnosis**
Opioid withdrawal is a clinical diagnosis. The withdrawal syndrome is a collection of signs and symptoms that occur after cessation of an
opioid agonist. The opioid toxidrome consists of respiratory depression, CNS depression, miosis, bradycardia, and decreased gut motility.\textsuperscript{60} The withdrawal syndrome predictably consists of the opposite of these symptoms, including irritability, insomnia, mydriasis, tachycardia, vomiting, and diarrhea. There can also be diaphoresis, piloerection, and yawning. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) lists criteria for the diagnosis of opioid withdrawal, as shown in Table 38.3.\textsuperscript{61} Clinicians in the ICU may find the DSM-5 criteria difficult to apply directly, given the many dynamic comorbid disease processes present in many ICU patients. Intensive care unit staff must be aware of iatrogenic opioid withdrawal symptoms; we recommend tracking a patient’s analgesia and sedative use for a fixed time interval (e.g., 12 or 24 hours) to identify appreciable decreases in use, which may indicate a patient’s increased risk of withdrawal. Long-term, high-dose, continuous administration of opioids is likely to place patients at increased risk of withdrawal later in their hospital stay. Intensive care unit clinicians should try to identify these at-risk patients before withdrawal symptoms start.

</table>
Severity and onset of withdrawal vary and are influenced by the dose of opioid and the duration of use. There is some evidence that route of administration also plays a role. In a retrospective analysis of heroin users who underwent acute withdrawal after inpatient admission for treatment, injection users had increased severity using the clinical opiate withdrawal scale.\textsuperscript{62} Onset of withdrawal varies depending on the half-life of the opioid. Agents having a longer half-life result in a later onset of withdrawal symptoms.\textsuperscript{63}

A less common, but more severe complication reported in the literature is takotsubo cardiomyopathy. A 60-year-old woman who stopped taking sustained-release morphine when her prescription ran out sought care when she began to have withdrawal symptoms. She developed chest pain and underwent cardiac catheterization, which did not reveal coronary disease. Echocardiography showed apical hypokinesis with basal hypercontractility and a reduced ejection fraction.\textsuperscript{64} Cases have also been reported after withdrawal of heroin, methadone, and buprenorphine.\textsuperscript{65–67}

Of importance, opioid withdrawal can occur in a variety of situations and not just in the heroin user. The rise in use of prescription opioids has resulted in a rise in abuse of these medications as well.\textsuperscript{68} Many patients are receiving chronic opioid therapy in the treatment of chronic pain and are therefore subject to the potential for withdrawal.

**Management**

Many methods are available in the management of opioid withdrawal. Definitive management is resuming opioid therapy. In non-intubated
patients, simply resuming the patient’s prehospital opioid medication regimen in those using opioids for chronic pain may stave off withdrawal symptoms. If avoiding withdrawal is the primary concern, lower opioid doses are usually sufficient to attenuate withdrawal symptoms, compared with analgesia dosing. In the critically ill, mechanically ventilated patient, opioids are commonly used for pain management, and they greatly reduce the risk of opioid withdrawal during the acute ICU admission.

Administering a long-acting opioid agonist such as methadone to act as a maintenance therapy is another option. Although this strategy when allowing the withdrawal syndrome to occur may be medically undesirable (e.g., in the pregnant mother), it has other complicating factors. Methadone can cause corrected QT (QTc) prolongation leading to fatal dysrhythmias. The potential for synergistic effects on the QT interval in the critically ill patient who may already be undergoing pharmacotherapy with agents that can prolong the QT makes this of particular concern. Legal concerns also make methadone potentially problematic. In some states, treating opioid withdrawal syndrome with methadone is only permissible as an adjunct to a primary medical or surgical problem. Table 38.4 provides dosing recommendations for opioid withdrawal management using methadone over 2 weeks. Twice-daily dosing is recommended to mitigate the risk of overdose on methadone initiation during days 1–4.

When opioid administration is not desired or is expected to be ineffective, such as after administering an opioid antagonist like naloxone, an α₂-adrenergic agonist can be used. These agents act at the α₂-adrenergic receptor, resulting in a decrease in neuronal transmission in a fashion similar to opioids. In this way, they decrease sympathetic outflow and reduce the withdrawal symptoms. Because they inhibit adrenergic tone, there is a risk of hypotension and bradycardia when using these agents. Clonidine, the most common medication of this class, is used with a dosing regimen of 0.1–0.2 mg orally every 4–6 hours (see Figure 38.3). A Cochrane review from 2014 found the α₂-adrenergic agonists clonidine and lofexidine to be superior to placebo in the treatment of opioid withdrawal.
growing interest in the use of dexmedetomidine for opioid withdrawal syndrome. It is similar to clonidine but is available as a titratable intravenous infusion with a greater affinity for the $\alpha_2$-receptor. Its use has been described in both adults and pediatric populations, and it has been shown to be safe in the critically ill. Given the limited data, dexmedetomidine has been recommended as adjunctive therapy until more research has been conducted to better define doses and limitations.

**BENZODIAZEPINE WITHDRAWAL**

**Background**
Benzodiazepines represent a class of medications commonly used for their anticonvulsant, anxiolytic, muscle-relaxant, and sedative properties. Benzodiazepines achieve these effects through binding of the GABAA receptor, binding between the $\alpha$ and $\beta$ subunits. Unlike other sedative-hypnotics (e.g., barbiturates), benzodiazepines require GABA to exert their functional effects. With long-term exposure to benzodiazepines and other GABAA agonists, GABA receptors may be down-regulated, making the neuronal cell more excitable, potentiating serious withdrawal syndromes.

### Diagnosis

Hallmark symptoms of benzodiazepine withdrawal include, but are not limited to, headaches, tremors, seizures, hallucinations, tachycardia, hypertension, diaphoresis, perceptual changes, and other findings common to critically ill patients not having benzodiazepine withdrawal. The usual course of benzodiazepine withdrawal follows three phases: first, there is a “rebound” of the symptom originally treated (e.g., insomnia, anxiety) lasting 1–4 days, depending on the pharmacokinetic properties of the individual agent; second, there is “full-blown” withdrawal, which may last up to 14 days; and third, there is a reemergence of the disease process originally treated. A clinical diagnosis may be made on the basis of a patient’s presentation, what is known of the patient’s medical history, and evaluation of the patient’s medication list or a controlled substance prescription database, when available. Severe withdrawal symptoms are more likely to be realized in patients using short-acting benzodiazepines; longer-acting benzodiazepines often contain active metabolites and result in a self-titrating effect. Patients with long-term use of benzodiazepines for several years may have a higher incidence of withdrawal symptoms; in one study, 27%–45% of diazepam or lorazepam users, for an average of 3.5 years, experienced withdrawal symptoms.

### Management

Commonly used sedation strategies in the ICU—as-needed administration of benzodiazepines or continuous infusions of propofol—attenuate the effects of benzodiazepine withdrawal, given their activation of the GABAA receptor. Current guidelines regarding pain

and agitation state that “sedation strategies using nonbenzodiazepine sedatives (either propofol or dexmedetomidine) may be preferred to sedation with benzodiazepines (either midazolam or lorazepam) to improve clinical outcomes in mechanically ventilated adult ICU patients.” Clinicians are advised to avoid continuous infusions of benzodiazepines; however, the phrasing of the guideline statement may lead clinicians to eschew any use of benzodiazepines for fear of worsening the delirium. Isolated, judicious use of as-needed benzodiazepine doses is highly unlikely to result in clinically relevant withdrawal symptoms. Given the pharmacologic differences between benzodiazepines and barbiturates, barbiturates are an effective strategy for patients with benzodiazepine withdrawal syndromes refractory to the simple reintroduction of benzodiazepines. Clinicians are cautioned to use barbiturates judiciously given the unfavorable safety profile of barbiturates relative to benzodiazepines. Table 38.5 provides a suggested regimen using diazepam for high-dose benzodiazepine withdrawal, defined as patients using greater than 50 mg/day of diazepam, or equivalent benzodiazepines. It is recommended to reduce doses on the basis of a patient’s tolerability; if a patient has withdrawal symptoms, experts recommend staying at the current dose of the taper until the patient tolerates the dose before further reduction and recommend against increasing the dose. For this reason, no precise time interval is recommended in Table 38.5; doses are reported as milligrams of diazepam, but equivalent benzodiazepine doses may certainly be substituted as indicated.

Table 38.6 is a compilation of suggested dose equivalents for oral benzodiazepines. Dose equivalency is an inexact science, and clinicians must account for interpatient variability together with differences in absorption, onset, protein binding, duration, and presence of pertinent active metabolite(s), together with the intended use of benzodiazepines. Appropriate monitoring is warranted with the administration of any benzodiazepine, regardless of the proposed equipotency (note the listed ranges for various benzodiazepine equivalents).

a
α₂-AGONIST WITHDRAWAL

Background
α₂-Adrenergic agonists and imidazoline derivatives (e.g., clonidine, guanfacine, tizanidine, dexmedetomidine) are treatments for a variety of medical diagnoses, including essential hypertension, attention-deficit/hyperactivity disorder, nasal congestion, Gilles de la Tourette syndrome, opioid withdrawal, spasticity, sedation, open-angle glaucoma, ocular hypertension, and tension-type headaches. This class of medications may be administered by oral (immediate- and extended-release formulations), intravenous, transdermal, and topical (nasal and ophthalmologic) routes. α₂-Adrenergic receptors are found in the central and peripheral nervous systems; the central effects of pre-synaptic agonism inhibit sympathetic outflow, resulting in bradycardia and hypotension.

Individual agents differ in their affinity for imidazoline and α₂-receptors, centrally and peripherally. The effects of each receptor subtype, together with the interplay between central α₂ and imidazoline receptors’ contributions to hypo-tension, have not been fully elucidated. Dexmedetomidine has high affinity for the α₂A-receptor, which is thought to provide the sedative effects of this and other α₂-agonists.

Although structurally dissimilar, α₂-agonists (particularly clonidine) attenuate the untoward effects of opioid withdrawal. Along these
same lines, the opioid-receptor antagonist naloxone reverses some effects of clonidine overdose.\textsuperscript{93} This effective overlap is hypothesized to stem from the similar effects of opioids and $\alpha_2$-agonists on potassium efflux in the locus ceruleus.\textsuperscript{94}

**Diagnosis**
Abrupt tapering or cessation of centrally acting $\alpha_2$-adrenergic agonists can induce withdrawal symptoms, including rebound hypertension, insomnia, delirium, irritability, tremor, and palpitations.\textsuperscript{90,95-100} Neuroleptic malignant syndrome, malignant hyperthermia, and serotonin syndrome are examples of potentially medication-induced symptoms that can easily be confused with $\alpha_2$-agonist withdrawal.\textsuperscript{99} Expanding beyond medication-induced causes, withdrawal can easily be overlooked in critically ill patients, given the nonspecific symptoms associated with an increase in sympathomimetic activity. Withdrawal symptoms from oral clonidine are expected to present within 16–72 hours of cessation.\textsuperscript{99,100}

A case of clonidine prescribed to alleviate withdrawal symptoms that
resulted in a prolonged stay in the ICU secondary to iatrogenic clonidine withdrawal highlights the need to keep α2-agonist withdrawal in the differential diagnosis. A patient on an intrathecal clonidine pump failure had severe withdrawal, which resulted in stress-induced cardiomyopathy, highlighting the serious consequences of clonidine withdrawal. Reports of dexmedetomidine withdrawal exist in the literature with features similar to clonidine and other α2-agonist withdrawal. These cases are associated with prolonged use of dexmedetomidine and can be managed through modalities described in the next section.

Management

α2-Agonists may be used for opioid withdrawal; conversely, morphine administration attenuates hypertension-associated α2-agonist withdrawal in rats. Because opioids are commonly administered in the ICU setting for analgesia, this theoretically may blunt some of the effects seen with α2-agonist withdrawal. More studies in humans are needed before opioids can be recommended solely for α2-agonist withdrawal. Given the safety concerns with opioids, regardless of a patient’s sex, we do not recommend using opioids solely to manage α2-agonist withdrawal. Mild cases of α2-agonist withdrawal may be managed nonpharmacologically with monitoring and supportive care. Cases increasing in severity may be managed either indirectly (with supportive measures) or directly (administration of the recently withdrawn agent or another α2-agonist). We are unaware of any reports using dexmedetomidine to manage withdrawal of an α2-agonist agent and do not recommend this approach at present. Clonidine has the largest body of literature regarding its withdrawal, partly because of its widespread use but also because of the pharmacokinetic properties relative to other α2-agonists (e.g., shorter half-life than guanfacine). The longer half-life agents are thought to self-taper and are hypothesized to have less severe withdrawal symptoms as a
CONCLUSION

The intent of this chapter was to provide a brief overview of the diagnosis, management, and potential treatments for patients with medication withdrawal; we recognize that this does not list all the potential medications that patients may withdraw from. Together with resource use, safety, cost, and other considerations, clinicians are encouraged to weigh the risks and benefits of withdrawal management in the ICU. An interdisciplinary approach to determining a patient’s actual medication use, with a well-trained clinical pharmacist readily available, is invaluable in identifying patients with potential medication withdrawal early in their ICU stay. Clinicians are encouraged to consider iatrogenic withdrawal syndromes in addition to prehospital medication withdrawal manifesting in the ICU. Medication withdrawal is rarely the cause for a patient’s ICU admission; however, if withdrawal is not identified, or is left untreated, it can further complicate the care of ICU patients. All members of the interdisciplinary ICU team should be aware of these potentially serious medical issues.

LEARNING OBJECTIVES

1. Describe the epidemiology, pathophysiology, clinical presentation (signs and symptoms), and management of myxedema coma, thyroid storm, adrenal insufficiency, hypercortisolism, and pheochromocytoma.

2. Outline nonpharmacologic and pharmacologic management of the disease states described above.

THYROID DISORDERS

Myxedema Coma
Definition and Epidemiology

Myxedema coma is the term given to the most severe presentation of profound hypothyroidism, which is often fatal despite therapy. Decompensation of the patient with hypothyroidism into a coma may be precipitated by a few drugs (e.g., amiodarone, lithium, and sunitinib), systemic illnesses (e.g., pneumonia), and other causes. Myxedema coma typically presents in older women in the winter months and is associated with signs of hypothyroidism, hypothermia, hyponatremia, hypercarbia, and hypoxemia. Treatment must be initiated promptly in an intensive care unit setting. Although thyroid hormone therapy is critical to survival, it remains uncertain whether it should be administered as thyroxine (T4), triiodothyronine (T3), or both. Adjunctive measures, such as ventilation, warming, fluids, antibiotics, vasopressors, and corticosteroids, may be essential for survival. Mortality in myxedema coma is estimated to be as high as 25%–65%, and early recognition is key to survival. The most typical precipitating factor is discontinuation of thyroid hormone replacement therapy, but this entity may be confused with other disease states such as hepatotoxicity. Careful attention to nonspecific complaints, myxedematous changes (e.g., puffiness and slowed mentation), and signs of dysfunction of any organ system, especially in older female patients, may lead to the ultimate correct diagnosis. Any history of thyroid disease and evidence of a surgical scar indicating thyroid surgery would be important. Myxedema coma must be recognized and treated emergently, usually before laboratory confirmation. Ventilatory support and thyroid hormone replacement are the two most important therapeutic maneuvers in the treatment of myxedema coma. In critical illness, thyroid function tests can be difficult to interpret, and some of these situations are summarized in Figure 39.1.

Pathophysiology

The underlying cause is a profound lack of T3 and T4; however, reduced deiodinase activity limiting the conversion of T4 to T3 may be a contributing factor. Some authors prefer intravenous T3, but others
consider treatment with T3 or T4 equivalent. Controversy exists whether the combination of T3 and T4 is better than single-agent therapy. An important drug-induced presentation for myxedema coma is the concurrent use of amiodarone.$^3$ It is thought that amiodarone interferes with the extrathyroidal production of T3 from T4.

**Clinical Presentation and Laboratory Diagnosis**

Typical signs and symptoms of hypothyroidism (dry skin, brittle nails, weight gain, and lethargy as well as hypothermia, hyponatremia, hypercarbia, hypoxemia, and altered mental status) must be present. The recent development of rating scales may aid in the rapid diagnosis of impending and frank myxedema coma. The scoring systems include a composite of alterations of thermoregulatory system, central nervous system (CNS), cardiovascular system, gastrointestinal (GI) system, and metabolic system and presence or absence of a precipitating event.$^5$ In the scale developed by Chiong et al., six variables were created for the screening tool: heart rate, temperature, Glasgow Coma Scale, thyroid-stimulating hormone (TSH), free thyroxine (FT4), and precipitating factors. The screening tool has a sensitivity and specificity of about 80%; however, this study was based on a small number of patients, and validation with a larger population is needed. The screening tool for assessing myxedema coma is presented in Table 39.1.

Typical laboratory abnormalities include low FT4 and high TSH in primary myxedema coma and low TSH in secondary myxedema coma. In a series of 10 patients, Chiong et al. found TSH to range from about 10 mU/mL to 140 mU/L. The FT4 concentrations ranged from undetectable to 1.7 ng/dL.$^5$ Although this is a small study, it makes the point that interpretation of thyroid tests must be done in the context of the patient’s clinical findings and with the understanding that concurrent disease states can influence thyroid tests and interpretation (see Figure 39.1).

**Treatment**
The mainstay of treatment is intravenous T3 or T4. Given that T3 is several times more potent than T4 and that T4 needs to be converted for the greater activity, T3 is the preferred drug. Although there are no randomized trials of intravenous T3, some authors recommend that T3 doses be normally administered at least 4 hours—and not more than 12 hours—apart. An initial intravenous dose of T3 is 25–50 mcg for emergency treatment and then a daily dose of 10–20 mcg. If the patient has underlying cardiovascular disease, this dose may be excessive. According to the author’s experience, oral dosing of T3 or T4 should be avoided because the bioavailability appears to be reduced, and normal absorption may not occur until several days after therapy is initiated. Once the clinical condition is stabilized, oral therapy may be resumed or initiated.

Figure 39.1  Patterns of thyroid function tests as
affected by nonthyroidal factors.

ATD = antithyroid drug; FDH = familial dysalbuminemic hyperthyroxinemia; FT3 = free triiodothyronine; FT4 = free thyroxine; NTI = non-thyroidal illness; TKI = tyrosine kinase inhibitor; TSH = thyroid-stimulating hormone.

Glucocorticoid support is empirically administered if adrenal gland failure has occurred simultaneously and to help stabilize blood pressure. Hydrocortisone 100 mg intravenously every 8 hours is the standard approach. Some patients require intravenous vasopressor support, and norepinephrine is a logical choice. Ventilatory support as needed may be required in some patients. Addressing other precipitating factors such as underlying infection and sepsis is also an important aspect of care. Because many patients present with hypothermia, warming should be considered with very low body temperatures (less than 95°F).

Assessment of Outcomes

The two most important parameters to gauge the success of treatment are improving mental status as measured by the Glasgow Coma Scale and increasing levels of thyroid hormones and reduction in TSH.

Thyroid Storm (Thyroid Crisis)

Definition and Epidemiology

Thyroid storm, also known as thyroid crisis, is thyrotoxicosis in the extreme. It is considered a medical emergency and presents with many of the typical symptoms associated with hyperthyroidism, except that thyroid storm must have the component of altered mental status. The most common trigger for thyroid storm is discontinuation or irregular use of antithyroidal agents.

Although the prevalence of thyroid storm is imprecise because of the rare nature of this disorder, recent retrospective cohort studies suggest a prevalence of about 0.2 per 100,000 population. Reports and
reviews from 2 decades ago suggested that mortality with thyroid storm ranged from 20% to 100%, but more recent reports have found mortality rates ranging from 9.5% to 11%. This disparity is most likely because of better and earlier recognition of patients at risk of thyroid storm and more aggressive and earlier treatment. The most common cause of death is heart failure or multiorgan failure (see Tables 39.2 and 39.3).

**Pathophysiology**

The underlying pathophysiology is similar to thyrotoxicosis and is mediated by thyroid-stimulating autoantibodies directed against the thyrotropin receptor on the surface of the thyroid cell. Binding of these immunoglobins to the receptor activates downstream G-protein signaling and adenylate cyclase in the same manner as TSH. Because the thyroid hormones T3 and T4 bind to receptors in many tissues in the body, the symptoms and clinical presentation can affect many organ systems.

**Clinical Presentation and Laboratory Diagnosis**

*IV = intravenous(ly); NSAID = nonsteroidal anti-inflammatory agent; PO = orally; q = every; TID = three times daily; QID = four times daily.*

Compared with thyrotoxicosis, the presenting symptoms are qualitatively similar but more severe (see Table 39.4). In addition to the common signs and symptoms of thyrotoxicosis, multiorgan system failure may be seen in thyroid storm, and altered mental status is a required feature for the diagnosis. Other notable differences between thyrotoxicosis and thyroid storm are GI and hepatic dysfunction (63% vs. 0%), the occurrence of atrial fibrillation (52% vs. 0%), and heart failure (33% vs. 0%).\(^7\) In addition to signs, symptoms, and laboratory features, two notable clinical rating scales have been useful in earlier and more valid identification of thyroid storm. The Burch-Wartofsky score and the Akamizu criteria have been used for identifying thyroid storm.\(^8,9\) The American Thyroid Association guidelines recommend a scale based on thermoregulatory dys-function, cardiovascular features, GI-hepatic dysfunction, CNS dysfunction, and precipitant history (Table 39.5).

Precipitating factors for thyroid storm include infection, trauma, surgery, radioactive iodine treatment, and withdrawal of antithyroid drugs or lack of treatment. Although clinical decompensation lasts an average of 72 hours, it may persist for up to 8 days.

**Treatment**

Treatment measures that should be instituted promptly include (1) suppression of thyroid hormone formation and release, (2) provision of antiadrenergic therapy, (3) administration of corticosteroids to preserve
vasomotor tone, and (4) treatment of associated complications or coexisting factors that may have precipitated the storm such as infection requiring antimicrobial treatment. Of the thioamides, propylthiouracil is preferred because it blocks new hormone formation and the peripheral conversion of T4 to T3. Methimazole has a theoretical advantage because of its longer duration of action. Because methimazole is teratogenic, it should not be used in patients who are pregnant or thought to be pregnant. If patients cannot take orally administered medications, the tablets can be crushed into a suspension and instilled by gastric or rectal tube; oral therapy is not possible. All iodine therapy should be administered 1–2 hours after propylthiouracil or methimazole has been given to prevent iodine-stimulated thyroid hormone synthesis.

Esmolol infusion would be most useful in patients with systolic heart failure for whom the state of compensation is unknown because the drug has a very short half-life and is rapidly cleared on discontinuation. Propranolol can be given orally or intravenously, but recall that it has a large first-pass effect with oral administration, and the intravenous dose is small (0.5–1 mg) in comparison. The target heart rate with antiadrenergic therapy is usually 90–100 beats/minute.

**Assessment of Outcomes**

Signs and symptoms of thyroid storm may begin to resolve within 8–12 hours, but the return to entirely normal heart rate, mental status, and so forth may take as long as 1–2 weeks. Thyroid-stimulating hormone will continue to be suppressed for weeks after clinical improvement; however, FT4 concentrations should normalize in 1–2 weeks. Once the patient has become clinically sound, doses of the thionamides can be reduced to maintenance levels and corticosteroids tapered and discontinued within a few days of clinical stability. Rigorous follow-up is necessary to prevent relapses, and precipitating factors should be avoided.

**PHEOCHROMOCYTOMA**

**Definition and Epidemiology**

Pheochromocytomas are catecholamine-producing neuroendocrine tumors that can be adrenal or extra-adrenal in origin. In patients with an established mutation or hereditary syndrome, the condition may manifest at a younger age than in those with sporadic disease. Pheochromocytoma can be associated with certain genetic syndromes such as MEN 2 (multiple endocrine neoplasia type 2), NF (neurofibromatosis), and VHL (von Hippel-Lindau) syndrome. Pheochromocytoma is diagnosed with biochemical confirmation of hormonal excess followed by anatomical localization (CT [computed tomography] or MRI [magnetic resonance imaging]).

Pheochromocytoma occurs in 2–8 patients in 1,000,000, with about 1,000 cases diagnosed yearly in the United States. It mainly occurs in young or middle-aged adults, though it presents earlier in hereditary syndrome. About 15% are extra-adrenal (located in any orthosympathetic tissue); of these, 9% are in the abdomen, and 1%
are located elsewhere. Some extra-adrenal pheochromocytomas are probably actually paragangliomas, but the distinction is only possible after surgical resection. Pheochromocytoma has an estimated prevalence of 0.1%–0.6% in individuals with hypertension; it is therefore a rare disease.

Pathophysiology
These tumors secrete high amounts of catecholamines, mainly epinephrine, plus norepinephrine to a lesser extent.

Clinical Presentation and Laboratory Diagnosis
The classic symptoms of pheochromocytoma are headache, palpitation, anxiety, and diaphoresis, and the tumor can occur at any age with equal sex distribution. Signs and symptoms of pheochromocytomas often include the following:

- High blood pressure
- Rapid or forceful heartbeat
- Profound sweating
- Severe headache
- Tremors
- Paleness in the face
- Shortness of breath

Modified from: Bahn et al. Hyperthyroidism and other causes of thyrotoxicosis; management guidelines of the American Thyroid Association and American Association of Clinical Endocrinologists. Thyroid 2011;21:593-646

Less common signs or symptoms may include the following:
- Anxiety or sense of doom
- Abdominal pain
- Constipation
- Weight loss

These signs and symptoms often occur in brief spells of 15–20 minutes. Spells can occur several times a day or less often. Blood pressure may be within the normal range or remain elevated between episodes.

Diagnosis depends on biochemical evidence of excessive production
of catecholamines. This is straightforward when test results are orders of magnitude above the concentrations expected in healthy individuals and those with essential hypertension. Equivocal results pose a management dilemma.

Evidence now indicates that initial screening for pheochromocytoma should include measurements of plasma-free metanephrines or urinary fractionated metanephrines. Liquid chromatography/mass spectrometry offers several advantages over other analytic methods and is the method of choice when measurements include methoxytyramine, the O-methylated metabolite of dopamine. The plasma test offers advantages over the urine test, although it is rarely implemented correctly, rendering the urine test preferable for mainstream use. To ensure optimal diagnostic sensitivity for the plasma test, reference intervals must be established for blood samples collected after 30 minutes of supine rest and after an overnight fast when measurements include methoxytyramine. Similarly, collected blood samples during screening, together with use of age-adjusted reference intervals, further minimize false-positive results. Extents and patterns of increases in plasma normetanephrine, metanephrine, and methoxytyramine can additionally help predict size and adrenal versus extra-adrenal locations of tumors, as well as the presence of metastases and underlying germline mutations of tumor susceptibility genes.10

One diagnostic test used in the past for a pheochromocytoma was to administer clonidine, a centrally acting $\alpha_2$-agonist used to treat high blood pressure. Clonidine mimics catecholamines in the brain, causing it to reduce the activity of the sympathetic nerves controlling the adrenal medulla. A healthy adrenal medulla will respond to the clonidine suppression test by reducing catecholamine production; lack of a response is evidence of pheochromocytoma.

**Treatment**

Surgical resection of the tumor is the treatment of first choice, by either open laparotomy or laparoscopy. Given the complexity of perioperative management, and the potential for catastrophic intra- and
postoperative complications, such surgery should be performed only at centers experienced in the management of this disorder. In addition to the surgical expertise that such centers can provide, they have the necessary endocrine and anesthesia resources. It may also be necessary to carry out adrenalectomy, a complete surgical removal of the affected adrenal gland(s). Either surgical option requires prior treatment with the non-specific and irreversible $\alpha$-adrenoceptor blocker phenoxybenzamine or a short-acting $\alpha$-antagonist (e.g., prazosin, terazosin, or doxazosin). Phenoxybenzamine is lipophilic and may have blood pressuring–lower effects for up to 7 days after dosing. Initial doses in adults are 10–20 mg/day and up to 20–40 mg/day for maintenance. Bioavailability is 20%–30%, and variation from patient to patient is to be expected. An alternative rapid-acting $\alpha_1$-antagonist is phentolamine. The initial dose is 5 mg intravenously/intramuscularly 1–2 hours before surgery, and repeated dosing if needed is 5 mg intravenously/intramuscularly every 2–4 hours. Unfortunately, the manufacturer has discontinued production of phentolamine, and currently, there is a shortage. Before surgery, the patient is conventionally prepared with $\alpha$-adrenergic blockade (over 10–14 days), and subsequently, additional $\beta$-adrenergic blockade is required to treat any associated tachyarrhythmias. In preoperative assessment, it is obligatory to monitor arterial blood pressure. Doing so permits the surgery to proceed while minimizing the likelihood of severe intraoperative hypertension (as might occur when the tumor is manipulated). Some authorities would recommend that a combined $\alpha$/ $\beta$-blocker such as labetalol also be given to slow the heart rate. Regardless, a $\beta_1$-receptor selective $\beta$-blocker such as atenolol must never be used in the presence of a pheochromocytoma because of the risk of such a treatment leading to unopposed $\alpha$-agonism and, thus, severe and potentially refractory hypertension. Studies have shown that labetalol is effective in the treatment of essential hypertension, renal hypertension, pheochromocytoma, pregnancy hypertension, and hypertensive emergencies. The patient with pheochromocytoma is invariably volume depleted. The chronically elevated adrenergic state
characteristic of an untreated pheochromocytoma leads to near-total inhibition of renin-angiotensin activity, resulting in excessive fluid loss in the urine and thus reduced blood volume. Hence, once the pheochromocytoma has been resected, thereby removing the major source of circulating catecholamines, a situation arises where there is both very low sympathetic activity and volume depletion. This can result in profound hypotension. Therefore, it is usually advised to “salt load” patients with pheochromocytoma before their surgery. This may consist of simple interventions such as consumption of high-salt food preoperatively, direct salt replacement, or administration of intravenous saline solution.

Assessment of Outcomes
The signs and symptoms of catecholamine excess (elevated heart rate and blood pressure, anxiety, etc.) should abate soon after surgery. As mentioned previously, blood pressure should be monitored closely, and a significant decrease in blood pressure should be anticipated because of the volume-depleted state. Normal saline or lactated Ringer solution should be titrated to maintain mean arterial pressure in a near-normal range.

ADRENAL DISORDERS

Adrenal Insufficiency (Addison Disease)

Definition and Epidemiology
Primary adrenal insufficiency or Addison disease most often involves destruction of all regions of the adrenal gland, leading to deficiencies in cortisol, aldosterone, and various androgens with elevation in corticotropin-releasing hormone and adrenocorticotropic hormone (ACTH). In developed countries, the most common cause is autoimmune destruction of the adrenal gland, whereas tuberculosis is more commonly the cause in developing countries. In chronic adrenal
insufficiency, adrenal crisis (AC) occurred in 8.3 crises per 100 patient-years. Precipitating causes were mainly GI infection, fever, and emotional stress (20% for each), but other stressful events (e.g., major pain, surgery, strenuous physical activity, heat, pregnancy) or unexplained sudden onset of AC (7%) were also documented. Given that corticosteroids are metabolized primarily through cytochrome P450 (CYP) 3A4, many drugs (e.g., carbamazepine, phenytoin) can increase the replacement doses needed. Patients with a previous AC were at a higher risk of crisis (odds ratio 2.85; 95% confidence interval [CI], 1.5–5.5; p<0.01). However, no further risk factors could be identified. Ten patients died during follow-up; in four cases, death was associated with AC (0.5 AC-related deaths per 100 patient-years).13

Another common cause of adrenal insufficiency is withdrawal of corticosteroid therapy, which is related to duration and amount of corticosteroid use. Stratified by administration form, percentages of patients with adrenal insufficiency ranged from 4.2% for nasal administration (95% CI, 0.5–28.9) to 52.2% for intra-articular administration (95% CI, 40.5–63.6). Stratified by disease, percentages ranged from 6.8% for asthma with inhalation corticosteroids only (95% CI, 3.8–12.0) to 60.0% for hematological malignancies (95% CI, 38.0–78.6). The risk also varied according to dose, from 2.4% (95% CI, 0.6–9.3) (low dose) to 21.5% (95% CI, 12.0–35.5) (high dose), and according to treatment duration, from 1.4% (95% CI, 0.3–7.4) (less than 28 days) to 27.4% (95% CI, 17.7–39.8) (more than 1 year) in patients with asthma.14

**Pathophysiology**

As described earlier, autoimmune destruction of the adrenal gland leading to deficiencies of cortisol, aldosterone, and androgens is the most common etiology in developed countries. Secondary adrenal insufficiency is usually a result of destruction of the pituitary gland caused by tumors or surgery. The principal difference is that aldosterone secretion remains intact so that normal potassium concentrations are observed, and ACTH is low or absent in contrast to primary adrenal insufficiency.
Clinical Presentation and Laboratory Diagnosis

The signs and symptoms of adrenal insufficiency are presented in Table 39.6. Common laboratory tests for diagnosis are presented in Table 39.7. In critically ill patients, laboratory monitoring and interpretation of tests can be somewhat difficult. It is important to consider the clinical presentation together with relevant laboratory tests to determine the best course of action for each patient.

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

**Treatment**

Adrenal crisis (Addison disease) is a medical emergency, and intravenous corticosteroids and volume resuscitation are of the utmost importance. Intravenous hydrocortisone 100 mg intravenous bolus should be followed by an infusion of 10 mg/hour. Some authors recommend 100 mg every 8 hours. Hydrocortisone is the preferred agent because it has both corticosteroid and mineralocorticoid activity (hydrocortisone 50 mg = fludrocortisone 0.1 mg). Once the patient has been stabilized, the dose may be tapered to 50 mg every 6–8 hours.

All patients will be in a volume-depleted state. Concurrent administration of normal saline or lactated Ringer solution at high flow rates will help restore a normal volume status and support blood pressure. Mineralocorticoid support with fludrocortisone 0.1 mg can be used in persisting hyperkalemia.

**Assessment of Outcomes**

Improved vasomotor tone after corticosteroid replacement will resolve hypotension, improve glycemic control, and maintain normal electrolyte status.

**Adrenal Excess (Cushing Syndrome)**

**Definition and Epidemiology**
Cushing syndrome (CS) results from the effects of supraphysiologic concentrations of glucocorticoids originating either from exogenous administration or less commonly from endogenous overproduction by the adrenal glands. Cushing syndrome has an incidence of 10–15 people per 1 million; however, studies of patients with diabetes, obesity, hypertension, and osteoporosis found a high prevalence of CS among these populations. Cushing syndrome is associated with high mortality if untreated, and the patient may survive only 4–5 years. The clinical manifestations of CS range from the distinctive clinical features (purple striae, facial plethora, proximal myopathy) to common conditions such as hypertension, obesity, and diabetes. Clinical practice guidelines recommend biochemical tests to screen patients for CS; however, the sensitivity and specificity of these tests vary, so a careful analysis must be performed to avoid misdiagnosis.

Pathophysiology
Cushing syndrome can be ACTH-dependent (80% of cases) or ACTH-independent. About 85% of ACTH-dependent cases are caused by a pituitary adenoma. Overproduction of ACTH causes bilateral adrenal hyperplasia. Adrenocorticotropic hormone can also be produced by ectopic ACTH-secreting tumors and non-neoplastic corticotropin hypersecretion, perhaps because of excess production of CRH (corticotropin-releasing hormone), accounting for the most cases of ACTH-dependent CS. Ectopic ACTH production can be caused by non-adrenal tumors such as small cell lung carcinoma.

Clinical Presentation and Laboratory Diagnosis
The clinical presentation and tests for laboratory diagnosis are presented in Table 39.8 and Table 39.9.

Treatment
The mainstay of treatment in CS when hypercortisolism is caused by a pituitary adenoma (called Cushing disease) is surgical removal of the
pituitary adenoma. If hypercortisolism is caused by adrenal adenoma or carcinoma, surgical removal of the affected adrenal gland or total removal in adrenal carcinoma is necessary if possible. Transsphenoidal surgery is used for Cushing disease to remove the pituitary tumor overproducing ACTH, and it is successful in about 90% of cases. After surgery, corticosteroid support will be needed, and the typical starting dosing is hydrocortisone 100 mg every 8 hours and gradual reduction for about 3 weeks. Adjunctive radiation may also be used if the entire tissue source cannot be removed. Pharmacologic therapy is palliative only but may useful for control of symptoms. Table 39.10 outlines the drugs used in CS. A combination regimen of ketoconazole and metyrapone is commonly used because these agents have synergistic mechanisms of action. Aminogluthethimide has fallen out of favor as a first-line drug because of adverse effects and high relapse rates. Drugs used for CS are not curative and are often used to prepare patients for surgery. Monotherapy is rarely used, and most patients will require combination therapy for better control of symptoms and laboratory parameters of CS.

<td>Maximum 3 g TID; take with food to decrease GI effects</td>
</tr>
</tbody>
</table>

q = every; TID = three times daily.
Assessment of Outcomes

Blood pressure should return to a near-normal level in a few days unless the patient has coexisting essential hyper-tension. Psychiatric symptoms should dissipate over days to weeks. Cortisol concentrations should drop abruptly with tumor removal, and patients will require long-term glucocorticoid support. Other pituitary hormones are likely to be affected as well, and thyroid supplementation will likely be needed. Other pituitary hormones may need to be replaced depending on the patient’s age. Adult patients usually need only glucocorticoid and thyroid hormone support.

REFERENCES

LEARNING OBJECTIVES

1. Define tumor lysis syndrome (TLS).
2. Identify patient- and tumor-related risk factors for developing TLS.
3. Describe preventive and treatment interventions for managing TLS.
4. Summarize the signs and symptoms of hypercalcemia of malignancy (HCM).
5. Review and evaluate treatment options for HCM.
6. Understand the pathophysiology of syndrome of inappropriate diuretic hormone (SIADH) in the setting of malignancy.
7. Describe management strategies for cancer-related SIADH.
8. Identify the signs and symptoms of superior vena cava syndrome (SVCS).
9. Summarize treatment options in patients with a diagnosis of SVCS.
10. Review the incidence, prognosis, and management of malignant spinal cord compression.

ABBREVIATIONS IN THIS CHAPTER
INTRODUCTION

Cancer treatments may lead to an increase in critical care conditions, in some cases necessitating urgent care and acute monitoring. These conditions often develop in many different manifestations but can often lead to critical if not urgent issues for patients with cancer. These disease states require rapid interventions because of their acute manifestation and potential onset of death or irreparable damage to the patient. Oncologic emergencies are defined as an acute condition caused by cancer or its treatment.

Oncologic emergencies are classified into specific categories: structural or obstructive emergencies, defined by the mass or size of a tumor in a space-occupying area (i.e., superior vena cava syndrome [SVCS], spinal cord compression); metabolic or hormonal emergencies (i.e., hypercalcemia and syndrome of inappropriate diuretic hormone [SIADH]); and secondary complications arising from treatment effects such as treatment-related oncologic emergencies (i.e., tumor lysis syndrome [TLS]).
Definition/Pathophysiology
The destruction of tumor cells either spontaneously or in response to chemotherapy results in TLS.\textsuperscript{1} Tumor lysis syndrome is most commonly associated with hematologic lymphomas and leukemias, including Burkitt lymphoma and acute lymphoblastic leukemia, but it has also been associated with low-grade lymphomas and solid tumors (Table 40.1).\textsuperscript{2} The massive efflux of the intracellular components from these malignant cells, including proteins, metabolites, and nucleic acids, overwhels normal homeostatic processes and can lead to life-threatening electrolyte abnormalities including hyperuricemia, hyperphosphatemia, hyperkalemia, and secondary hypocalcemia.\textsuperscript{1}

Hyperuricemia occurs as a direct consequence of the release of nucleic acid by-products when tumor cells are lysed. The DNA is metabolized to pyrimidine and purine nucleotides, and the latter is converted to hypoxanthine. Xanthine oxidase then mediates the conversion of hypoxanthine to xanthine and the conversion of xanthine to uric acid.\textsuperscript{3,4} Under normal homeostatic processes, renal excretory mechanisms facilitate the clearance of uric acid; uric acid is filtered by the glomerulus, reabsorbed by the proximal tubule, and then secreted by the distal tubule.\textsuperscript{5} However, renal excretory capacities become saturated in the setting of TLS, resulting in the precipitation of uric acid crystals within the tubular infrastructure, obstruction with decreased urine flow, vasoconstriction, and acute kidney injury.\textsuperscript{6}

Tumor cells harbor intracellular phosphates at 4 times the concentration of normal cells.\textsuperscript{7} The rapid release of phosphate from tumor cells in response to chemotherapy and the potential for concomitant uric acid nephropathy overwhelm normal renal excretory capacities for phosphate. The resultant hyperphosphatemia can manifest clinically as nausea, vomiting, lethargy, or mental status changes.\textsuperscript{1,2,7}

Hypocalcemia occurs secondary to hyperphosphatemia and the formation of calcium phosphate precipitates. Calcium phosphate
precipitates can deposit within various tissue beds, including the cardiac vasculature and the kidneys, thereby potentiating the risk of acute kidney injury and serious cardiac arrhythmias. Hypocalcemia can also cause neuromuscular irritability and seizures.\(^1\)

Tumor cells also harbor high concentrations of potassium, and the rapid release of potassium from lysing tumor cells can overwhelm normal metabolic processes. In the setting of hyperuricemia-induced acute kidney injury and calcium phosphate nephropathy, renal clearance of potassium is compensated, thereby increasing serum concentrations of potassium.\(^3\) Elevated potassium can present as nausea, vomiting, or muscle weakness and can also cause serious electrocardiographic (ECG) changes, specifically peaked T waves and widening of the QRS complex. Hyperkalemia can also manifest as ventricular arrhythmias, which can lead to sudden cardiac death when coupled with secondary hypocalcemia.\(^{1,2,7}\)

Tumor lysis syndrome is classified as laboratory or clinical TLS as defined by the Cairo and Bishop criteria. Laboratory TLS (LTLS) requires at least a 25% change from baseline for two or more of the following laboratory parameters: hyperuricemia (greater than 8.0 mg/dL), hyperphosphatemia (greater than 4.5 mg/dL), hyperkalemia (greater than 6.0 mmol/L), and hypocalcemia (corrected calcium less than 7.0 mg/dL). These metabolic changes are expected to occur simultaneously at least 3 days before or 7 days after initiating treatment as part of the definition of LTLS (Table 40.2). Clinical TLS is defined by the presence of at least one clinical manifestation of TLS including renal insufficiency, arrhythmias, and seizures in addition to LTLS.\(^{2,8}\)

*LTLS requires two or more metabolic abnormalities occurring within the same 24-hr period*
window either 3 days before or up to 7 days after initiating chemotherapy.

bCTLs requires the presence of LTLS plus one of the clinical manifestations. ULN = upper limit of normal.

Incidence/Epidemiology
Tumor lysis syndrome typically occurs in response to the treatment of hematologic malignancies, specifically high-grade lymphomas—most commonly, Burkitt lymphoma and acute lymphoblastic leukemia—but it has also been associated with low-grade lymphomas, including indolent non-Hodgkin lymphoma, Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma and solid tumors with high tumor burden including metastatic breast cancer, small cell lung cancer, melanoma, and non– small cell lung cancer.\(^2,3,8,9\)

Tumor lysis syndrome can also occur spontaneously in the absence of treatment. Spontaneous TLS is usually observed in the setting of Burkitt lymphoma but has also been associated with other hematologic malignancies and solid tumors. Although the risk factors for developing spontaneous TLS are not clearly defined, spontaneous TLS is typically associated with a poor prognosis compared with classic TLS.\(^2,3,5\)

Workup of TLS should be considered when there is a malignancy with unexplained reason of acute kidney failure.

Risk factors for TLS include both tumor- and patient-specific factors. Tumor-specific risk factors include tumor burden, which is related to the bulkiness of the tumor mass, and the extent of tumor infiltration and/or metastasis and cell lysis potential, which is related to lactate dehydrogenase concentrations, the rate of cell proliferation, and the sensitivity of the tumor to chemotherapy including Burkitt lymphoma, lymphoblastic lymphoma, and B-cell acute lymphoblastic leukemia. The intensity of chemotherapy is also grouped with tumor-related factors when assessing the risk of TLS; the higher the intensity of the chemotherapy, the greater the potential for tumor cell lysis. Patient-specific factors can also determine the risk of TLS and include baseline nephropathy, dehydration, and hypotension, all of which can result in decreased urine flow and increase the propensity for uric acid and/or
calcium phosphate precipitation (Table 40.1).\textsuperscript{1,2,8}

Assessment of risk factors allows for stratification of patients according to predicted risk of TLS and can direct the management strategy of TLS. Most risk assessment models center on the underlying malignancy and stratify patients as high, intermediate, or low risk depending on the presence and/or degree of tumor-related manifestations and baseline patient-specific characteristics.\textsuperscript{2,8}

The risk stratification model proposed by Cairo et al. stratifies patients according to the underlying malignancy (Table 40.3) and extent of metastasis/bulkiness of the disease, type of chemotherapy, and preexisting renal dys-function, among other factors. This model, however, does not directly outline treatment recommendations for each stratification group, thereby creating challenges when applying it to clinical practice for the management of TLS.\textsuperscript{2,8}

**MANAGEMENT OF TLS**

The goal of managing TLS is to prevent the potentially serious renal, neurologic, and cardiac sequelae that can result from TLS. The initiation of preventive and treatment interventions is directed by the initial risk assessment of patients at risk of these serious complications.

**Prophylaxis**

**Hydration/Urine Output Goals**

All patients at risk of TLS and without contraindications to aggressive fluid therapy should be initiated on intravenous hydration therapy. Fluids should be initiated at least 24–48 hours before chemotherapy and continued through the completion of chemotherapy. The role of fluids in the setting of TLS is 2-fold: (1) dilute the extracellular space to reduce serum concentrations of potassium, phosphate, and uric acid; and (2) increase renal blood flow and filtration, promote high urine output, and prevent the accumulation of nephrotoxic calcium phosphate and uric
acid precipitates within the kidneys.\textsuperscript{2,5,7,10} Fluid therapy should be titrated as needed to achieve a target urine output of 80–100 mL/m\textsuperscript{2}/hour or maintained at 1–2 times fluid maintenance requirements. Loop diuretics can be considered if target urine outputs are not achieved with continuous hydration therapy.\textsuperscript{2,7,10}

Historically, urine alkalinization with sodium bicarbonate was recommended as part of the management of TLS. Although mechanistically, urine alkalinization increases the renal clearance of uric acid, the solubility of uric acid precursors, including hypoxanthine and xanthine, is decreased. The risk of xanthine nephropathy increases, particularly in the setting of the concomitant use of allopurinol, which acts as a competitive inhibitor of xanthine oxidase and prevents the conversion of hypoxanthine and xanthine to uric acid, ultimately increasing the concentration of these uric acid precursors. Furthermore, urine alkalinization decreases the solubility of calcium phosphate, thereby exacerbating the underlying risks associated with calcium phosphate precipitation. Therefore, given the risk of xanthine and calcium phosphate precipitation, sodium bicarbonate is no longer recommended for the prevention of TLS.\textsuperscript{1,3,5,7,10,11}

**Allopurinol**

Allopurinol is readily used in combination with fluid therapy for preventing TLS. By blocking xanthine oxidase, allopurinol decreases the conversion of hypoxanthine and xanthine to uric acid (Figure 40.1). The role of allopurinol in managing TLS, however, is limited to prevention, given its negligible effects on existing uric acid.\(^1\),\(^5\),\(^7\),\(^10\),\(^11\)

The recommended dose of allopurinol is 100 mg/m\(^2\) orally every 8 hours or 10 mg/kg/day orally divided every 8 hours. Allopurinol is converted to oxypurinol, which is an active metabolite that also serves as a xanthine oxidase inhibitor.\(^2\),\(^10\) The onset of action of xanthine oxidase activity, however, for both allopurinol and oxypurinol, is delayed; therefore, normalization of uric acid concentrations may be prolonged, ultimately delaying the initiation of chemotherapy.\(^10\)
Allopurinol should be dose reduced by 50% for patients with renal insufficiency. The concomitant use of allopurinol and purine analogs (i.e., mercaptopurine, azathioprine) and purine-based chemotherapy should be avoided because allopurinol may prevent the degradation of
these purine analogs and increase treatment-related toxicities (i.e., bone marrow suppression). Alternatively, purine analogs can be dose reduced by 70% when used concomitantly with allopurinol.\textsuperscript{2}

Allopurinol is usually well tolerated but has been associated with hypersensitivity reactions including, but not limited to, Stevens-Johnson syndrome and toxic epidermal necrolysis. These reactions may manifest as fever and rash and may have a delayed onset. In addition, the risk of obstructive uropathy is inherent with the use of allopurinol, given the increased concentrations of xanthine and hypoxanthine, and should be closely monitored for the duration of therapy.\textsuperscript{1,2,3,5,7,10}

**Treatment**

**Rasburicase**

Rasburicase, a recombinant urate oxidase, has become the mainstay of therapy for treatment of TLS given its ability to readily degrade existing uric acid (Figure 40.1). Rasburicase enzymatically converts uric acid to allantoin, a formulation of uric acid that is highly soluble and readily excreted by the kidney.\textsuperscript{2,3,5,10}

Rasburicase is U.S. Food and Drug Administration approved for managing TLS in patients with leukemia, lymphoma, and solid tumors with baseline hyperuricemia or expected hyperuricemia after initiating chemotherapy. The initial recommended dose of rasburicase was 0.15–0.2 mg/kg as a daily 30-minute intravenous infusion, given up to 7 days; however, new recommendations have amended this to include rasburicase 0.1–0.2 mg/kg as a single dose for managing TLS.\textsuperscript{11}

Abbreviated dosing strategies are equivocal for fixed- and flat-dosing schedules, including rasburicase 6- and 3-mg dosing, and although this scheduling has not been incorporated into the guidelines, the flat-dose scheduling is often used in clinical practice.\textsuperscript{12–16} Treatment duration depends on reducing uric acid concentrations and achieving uric acid control.\textsuperscript{2,10} Given the comparative efficacy of weight-based dosing in normalizing elevated uric acid concentrations and the high cost of rasburicase, fixed dosing serves as a cost
strategy for managing TLS.\textsuperscript{12–16}

Rasburicase, as an enzyme, continues to degrade uric acid in blood samples and can lead to falsely low readings of uric acid. The samples should therefore be collected in pre-chilled tubes and maintained on ice en route to the laboratory to ensure an accurate analysis of uric acid concentrations.\textsuperscript{2,17}

Rasburicase is usually well tolerated with the exception of hypersensitivity reactions that can manifest as pruritus and dermatologic reactions. Of note, all patients should be screened for glucose-6-phosphate-dehydrogenase (G6PD) deficiency before treatment with rasburicase. Patients with G6PD deficiency are unable to metabolize the hydrogen peroxide by-products produced by the conversion of uric acid to allantoin and are at increased risk of hemolytic anemia and methemoglobinemia. Glucose-6-phosphate dehydrogenase deficiency is most commonly observed among patient populations of Mediterranean, Southeast Asian, and African American descent.\textsuperscript{2,17}

**Electrolyte Monitoring/Management**

Monitoring is recommended for the duration of the risk of TLS. Consensus guidelines recommend increasing the frequency of electrolyte monitoring, including uric acid, phosphate, potassium, and calcium, depending on the risk of TLS: every 4–6 hours, every 8–12 hours, and once daily for high-, intermediate-, and low-risk TLS, respectively. Continuous cardiac monitoring is recommended for patients at high risk of TLS. In addition, parameters to assess for renal function, including serum creatinine and urine output, should be monitored continuously. The correction of electrolyte abnormalities is recommended before initiating chemotherapy. In addition, prompt therapeutic interventions are recommended for any symptomatic manifestations of these biochemical derangements.\textsuperscript{1-3,5,7,8}

**Hyperphosphatemia**

Hydration is usually sufficient to correct elevated phosphate
concentrations. Oral phosphate binders, including aluminum hydroxide, lanthanum carbonate, and sevelamer hydroxide, can be considered for treating hyperphosphatemia, although their efficacy is limited by the slow onset of action required to achieve target phosphate concentrations. Phosphate binders inhibit the absorption of phosphate through the gastrointestinal tract.

**Hypocalcemia**
Treatment of asymptomatic hypocalcemia is not recommended. Instead, it is more appropriate to correct the underlying cause of hyperphosphatemia. However, symptomatic hypocalcemia manifesting as severe cardiac arrhythmias or seizures should be treated with intravenous calcium gluconate.

**Hyperkalemia**
The goal of treating hyperkalemia in the setting of TLS is to prevent cardiac sequelae. An oral ion-exchange resin, sodium polystyrene sulfonate, can be considered for patients with asymptomatic hyperkalemia, although efficacy is limited by the slow onset of action and limited therapy duration, given the risk of colonic necrosis with repeated doses. Symptomatic hyperkalemia requires prompt intervention; insulin (with glucose), β-agonists, and sodium bicarbonate will facilitate the intracellular shift of potassium from plasma, and are all treatment modalities that can be considered.

Elimination of exogenous potassium sources should also be considered. In addition, any medications known to inhibit renal secretion of potassium should be discontinued, including potassium supplements, potassium-sparing diuretics, aldosterone antagonists, and nonsteroidal anti-inflammatory agents.

Careful monitoring for ECG changes is indicated, and calcium gluconate can be considered for cardiac arrhythmias for membrane stabilization.

**Renal Replacement Therapy**
Renal replacement therapy is recommended as a definitive treatment modality for TLS, and it should be considered for TLS-induced kidney injury in the setting of severe metabolic instabilities despite prophylactic measures. Continuous renal replacement therapy includes hemodialysis, hemofiltration, and hemodiafiltration and is the preferred method of dialysis to allow for continuous and targeted removal of solutes released by lysing tumor cells. Dialysis should be continued until renal function is fully recovered, which may require weeks of therapy.\textsuperscript{1-3,5,7,8}

\textbf{HYPERCALCEMIA}

Hypercalcemia of malignancy (HCM) is often an acute manifestation, with outcomes that yield a poor prognosis with a correlated high mortality rate. Hypercalcemia of malignancy has been reported to occur in around 10\%–20\% of patients with cancer. Outcomes for patients with a diagnosis of HCM are reported to range from only 2 months to 6 months from the initial diagnosis, with up to half of the patients dying within 1 month.\textsuperscript{2} The incidence of HCM is low at initial presentation of a cancer diagnosis, but it increases with progression of disease.\textsuperscript{18} Hypercalcemia of malignancy is associated with several disease states including breast cancer, multiple myeloma, squamous cell carcinoma of the lung, squamous cell carcinoma of head and neck, renal cell carcinoma, lymphoma, and other malignancies including ovarian cancer, pancreatic cancer, and unknown primary cancer.\textsuperscript{18} Many pathophysiologic mechanisms may contribute to HCM (Figure 40.2).

Cancer-associated hypercalcemia is classified into four different types: local osteolytic hypercalcemia, humoral HCM, 1,25(OH)-secreting lymphomas, and ectopic hyperparathyroidism.\textsuperscript{19} Local osteolytic hypercalcemia is caused by an increase in bone resorption by osteoclasts, leading to local destruction of the bone by the tumor. In turn, this releases the calcium deposits of the bone into the serum. Certain tumors, including solid cancers, non-Hodgkin lymphoma, and blast phase chronic myeloid leukemia, secrete parathyroid hormone
(PTH)-related protein, which can mimic PTH by stimulating the type 1 PTH receptor.\textsuperscript{20,21} Parathyroid hormone–related protein is a monomeric amino acid peptide sequence that mimics PTH protein structure. The protein is normally secreted by neuroendocrine, epithelia, and mesodermal tissue. Another known cause of HCM, although to a lesser extent, is by lymphoma tumors, which may directly secrete 1,25-dihydroxyvitamin D (calcitriol).\textsuperscript{22} The release of calcitriol leads to increased activation of osteoclast bone resorption and calcium reabsorption in the intestine. The last cause of HCM, the ectopic secretion of PTH by tumors, has been reported in case studies but is rarely observed.\textsuperscript{23}

**Signs and Symptoms**

Signs of HCM may often vary depending on patient characteristics and tolerance. Patients’ calcium concentrations may be at higher concentrations of the normal calcium range without symptoms of hypercalcemia. These symptoms often vary in nature, but they bring to light the mnemonic “stones, bones, abdominal moans, and psychic groans” used to guide most symptoms that reflect hypercalcemia (Table 40.4).

Patients may have neuromuscular adverse effects, which can include fatigue, confusion, and muscle weakness, constipation, and tetany. Gastrointestinal adverse effects can include nausea, vomiting, abdominal pain, appetite suppression and cachexia, and pancreatitis. Renal effects commonly seen are polydipsia, nocturia and polyuria, and nephrolithiasis caused by hypercalciuria from the kidneys. Renal adverse effects can also include dehydration and nephrocalcinosis. Cardiovascular adverse effects can be noted on ECG readings including a shortened QT interval as well as hyper-tension, with rare report of arrhythmias. Bone pain is also common in patients with malignancy because of the release of calcium of the bone by osteoclasts.\textsuperscript{19}

**Diagnosis**
Diagnoses of hypercalcemia are often based on the total serum calcium concentration. Because 40%-45% of serum calcium is bound to proteins, predominantly albumin, the serum calcium concentration must be corrected in the presence of hypoalbuminemia or hyperalbuminemia.\textsuperscript{19} Measuring the serum ionized calcium concentration can also be useful and does not need to be corrected for abnormalities in albumin concentrations.

Although malignancy is often clinically evident and diagnosed before it leads to symptomatic hypercalcemia, it is still important to distinguish cancer-related hypercalcemia from hypercalcemia as the result of primary hyperparathyroidism or other causes (e.g., excess vitamin A or D, medications, thyrotoxicosis).\textsuperscript{22} It is also possible that more than one etiology is present. Thus, determining the reason for hypercalcemia is essential to treating the underlying cause. Hypercalcemia presents with the same general symptomology according to condition of severity, but a differential diagnosis can be done by ruling out other causes through a careful history and laboratory testing (e.g., intact PTH concentrations or PTH-related protein secretion).

\textbf{Treatment}
Managing hypercalcemia largely depends on its severity, which generally correlates with the measured serum calcium concentration.\textsuperscript{19} Regardless of the degree of severity, it is crucial that patients minimize any factors that may contribute to raising the serum calcium concentrations. This may involve avoiding certain medications (e.g., thiazide diuretic, calcium or vitamin D supplements), maintaining sufficient fluid intake, or remaining ambulatory.\textsuperscript{19,23}

For asymptomatic patients with mild hypercalcemia, removal of any contributing factors may be enough to correct the issue. If patients are symptomatic or their total serum calcium is closer to 12 mg/dL, normal saline hydration can be initiated (Table 40.5). The rate of hydration can be 200–500 mL/hour going up to 4–6 L/day. However, factors such as the patient’s current level of dehydration and any comorbidities like congestive heart failure or renal insufficiency should be considered. In addition to tracking the serum calcium, electrolytes and urine output
should be monitored, and care should be taken to make sure the patient does not become fluid overloaded. Although loop diuretics are commonly paired with saline hydration therapy to increase the excretion of calcium, evidence for their efficacy outside the setting of fluid overload is more limited.\textsuperscript{19}

Patients with moderate hypercalcemia can be initiated on intravenous bisphosphonate therapy in addition to general supportive measures and saline hydration. Bisphosphonates inhibit osteoclast-mediated resorption and the release of calcium from the bone. They are given intravenously for hypercalcemia because of their poor absorption profile when taken orally. Zoledronic acid (4 mg intravenously given over 15 minutes) and pamidronate (given over 4–6 hours, see Table 40.4) are commonly used for this indication.\textsuperscript{23,24} Serum calcium decreases within 24–48 hours after administration, and the maximum effect can be seen within 3–7 days. Although zoledronic acid has a significantly higher response rate in some studies and can be given for a shorter period, this must be weighed against its much higher cost compared with pamidronate.\textsuperscript{25} With both medications, serum creatinine and other serum electrolytes should be monitored as well as the serum calcium concentration.

For severe hypercalcemia, treatment should be initiated immediately with normal saline hydration, a bisphosphonate, and calcitonin. Although it has a more transient and smaller magnitude of effect than do bisphosphonates, calcitonin is given in this setting because of its quicker onset of action (decreases seen within 2 hours after administration) compared with bisphosphonates. It antagonizes PTH, thereby decreasing osteoclast activity and promoting renal excretion of calcium, and is given at an initial dose of 4 international units/kg twice daily as either an intramuscular or a subcutaneous injection. Prolonged exposure to calcitonin can increase the risk of tachyphylaxis, and often, a maximum threshold of 2–3 days is considered for use in treatment.

In patients who are refractory to bisphosphonate therapy or who have marked renal insufficiency, denosumab may provide another option for treating HCM. Denosumab decreases osteoclast formation and activation by binding to the receptor activator of nuclear factor-κB ligand (RANKL) and preventing its interaction with the receptor activator of nuclear factor-κB (RANK) on the osteoclast cell surface. It is given as a subcutaneous injection of 120 mg every 4 weeks. During the first month of therapy, additional doses of 120 mg are given on days 8 and 15. A response is typically seen within 9 days, but a complete response may not occur until 3 weeks after administration.

Other therapies that can aid in managing hypercalcemia but that are used less commonly include glucocorticoids, which decrease calcitriol production; gallium nitrate, which inhibits bone resorption and promotes formation; cinacalcet, which is a calcimimetic that sensitizes the calcium-sensing receptor on the parathyroid gland and in turn lowers PTH synthesis; and dialysis. How-ever, all of these therapies are limited by either efficacy or adverse effects.

Of note, although these measures all decrease the serum calcium concentration, the cause of the hypercalcemia must ultimately be
addressed. For hypercalcemia caused by malignancy, treatment of the cancer should be implemented as appropriate to prevent further recurrences of hypercalcemia and provide for a more sustained response.

SYNDROME OF INAPPROPRIATE DIURETIC HORMONE

Definition/Pathophysiology

Hyponatremia is defined as total body water excess in relation to serum sodium and is the most common electrolyte disorder associated with malignancy. Hyponatremia can further be classified as mild (less than 135 mmol/L), moderate (less than 130 mmol/L), or profound (less than 125 mmol/L) depending on serum sodium concentrations. The presentation of hyponatremia is a spectrum of clinical symptoms ranging from mild nausea and vomiting to severe neurological deficits including the potential for seizure, coma, or respiratory arrest. Hyponatremia is considered a poor prognostic factor and is associated with significant mortality and morbidity, including increased length of hospital stay. Syndrome of inappropriate diuretic hormone is the most common cause of cancer-related hyponatremia.\textsuperscript{28,29}

Ectopic production of arginine vasopressin (AVP) by tumor cells serves as the underlying mechanism for SIADH in the setting of malignancy. Under normal physiologic controls, AVP functions to regulate fluid and electrolyte balance and maintain effective plasma osmolality. Arginine vasopressin is stimulated in response to plasma hyperosmolality or hypovolemia. In the setting of increased effective plasma osmolality, osmoreceptors are activated within the hypothalamus, stimulating the release of AVP from the posterior pituitary. Arginine vasopressin then binds to $V_2$ receptors within the basolateral membrane of collecting tubules of the kidney and stimulates the production of cyclic adenosine monophosphate (cAMP). Cyclic adenosine monophosphate mediates the synthesis of aquaporin-2 water channels, which are inserted within the walls of the collecting-duct of the kidney to ultimately increase water permeability and
reabsorption and reestablish normal serum osmolality. Corrected serum osmolality then serves as a negative feedback for continued AVP secretion and activity.\textsuperscript{28,30-32}

### Table 40.5 Current Treatments for Hypercalcemia of Malignancy
Decreased effective blood volume also serves as a stimulus for increased AVP. Baroreceptors within the vasculature of the heart sense circulating blood volume, and in the setting of hypovolemia, AVP is released, which binds to V₁ receptors within blood vessels and causes vasoconstriction in an effort to increase systemic vascular resistance. In the setting of malignancy, production of AVP is ectopic and secreted in the absence of plasma hyperosmolality or hypovolemia, thereby creating a dilutional hyponatremia with increased total body weight and maintained serum sodium concentrations.

### Incidence/Risk Factors
Syndrome of inappropriate diuretic hormone is most commonly associated with small cell lung cancer with an incidence of 11%–15%. Syndrome of inappropriate diuretic hormone has also been reported...
among other subtypes of lung cancer including adenocarcinomas, squamous cell carcinomas, and large cell carcinomas, although incidence is limited to case reports. Head and neck cancer is the second most common malignancy associated with SIADH, particularly head and neck cancers of squamous cell histology. The incidence of SIADH among other cancer types is rare but has been reported for cervical, breast, and prostate cancer and hematologic malignancies including Hodgkin lymphoma, non-Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma.28,31-33

Beyond the ectopic production of AVP by these specific cancer types, many chemotherapy agents used in treating malignancy may cause SIADH. Chemotherapy agents including the vinca alkaloids, specifically vincristine and vinblastine; platinum agents, including cisplatin and carboplatin; and alkylating agents, including cyclophosphamide and melphalan, potentiate the hyponatremic effects of SIADH by increasing the production of AVP. Immunomodulator agents including interferon and aldesleukin have also been reported to cause hyponatremic effects consistent with SIADH.28,31,34 Syndrome of inappropriate diuretic hormone may also be related to the supportive care interventions used for palliation of patients with cancer, including analgesic medications, specifically opioids and nonsteroidal anti-inflammatory agents, antidepressants, and aggressive hydration therapy required with specific chemotherapy agents to mitigate potentially toxic adverse effects.31,35

Clinical Presentation/Symptoms
The clinical presentation of SIADH is a wide spectrum of neurological symptoms. The severity of the neurological symptoms is related to the acuity of the change in the plasma sodium concentration, degree of the hyponatremia, and ability of the adaptive mechanisms within the brain to respond to and compensate for changes in effective plasma osmolality. Normal compensatory mechanisms will respond to decreased plasma osmolality related to hyponatremia by increasing the transit of water and limiting the transit of organic solutes into the cerebral space to effectively maintain the normal total brain volume.
These compensatory mechanisms become overwhelmed in the setting of acute or severe hyponatremia and cannot provide for timely correction of hyponatremia, thereby increasing the risk of cerebral edema and irreversible neurological damage. Symptom severity is determined by the degree of cerebral edema; mild hyponatremia is characterized by headache, weakness, and decreased concentration, whereas profound hyponatremia is characterized by altered mental status, hallucinations, seizures, obtundation, and respiratory arrest.\textsuperscript{28,29,31}

**Management of SIADH**
The goal of managing SIADH in the setting of malignancy is to prevent the potentially serious neurological complications caused by severe hyponatremia. Optimal management of tumor-related SIADH is treatment of the underlying malignancy. Given the delayed therapeutic effects of chemotherapy to correct hyponatremia related to SIADH, other treatment modalities can be considered to optimize sodium/water balance. Hypertonic (3\%) saline is recommended for treating symptomatic SIADH and can be administered as a continuous infusion at a rate of 1–2 mL per kilogram of body weight per hour or as 150-mL boluses every 20 minutes with repeat 150-mL infusions continued only until symptoms have resolved or serum sodium has increased by 5 mmol/L. Careful and periodic monitoring of changes in serum sodium is recommended to reduce the risk of overcorrection, including osmotic demyelination, which can be characterized by severe lethargy, motor weakness and paralysis, confusion, behavioral changes, and even coma.\textsuperscript{30} After the first hour of therapy, it is recommended to discontinue the hyper-tonic saline if the serum sodium concentration has increased by 5 mmol/L and symptoms have improved and to transition to treatment aimed at the underlying cause of SIADH with continuous monitoring of serum sodium for the first 24 hours. Correction of sodium should be limited to 10 mmol/L for the first 24 hours and 8 mmol/L every 24 hours thereafter to decrease the risk of osmotic demyelination. If symptoms do not improve despite a serum sodium increase of 5 mmol/L within the first hour of therapy, hypertonic
saline can be titrated to increase serum sodium by an additional 1 mmol/L not to exceed 130 mmol/L (even if symptoms persist); however, other causes of hyponatremia should be investigated.\textsuperscript{28,29,31} Various formulas are available for calculating the initial rate of hypertonic saline. The mostly widely accepted formula, the Adrogue-Madias model, aims to achieve a 1-mmol/L/hour increase in serum sodium, although correction speed may surpass that predicted by the equation, thereby necessitating careful monitoring.\textsuperscript{29–30}

All patients with asymptomatic SIADH and without contraindications to aggressive fluid restriction should be limited to 500 mL below the average daily urine output. Fluid restriction is an effective therapeutic strategy for correcting hyponatremia in the setting of SIADH, although compliance may be challenging, ultimately necessitating the initiation of other pharmacotherapeutic interventions for tumor-related SIADH (Table 40.6). Demeclocycline is a tetracycline derivative that inhibits the formation of cAMP, thereby blocking the downstream-mediated effects of AVP on the kidneys. At the recommended dose of 600 mg orally once daily, demeclocycline is generally well tolerated, although higher doses have been associated with renal toxicity.\textsuperscript{28,29,31,36}

Arginine vasopressin receptor antagonists block the binding of AVP to the V\textsubscript{2} receptors within the renal collecting ducts, thereby increasing water excretion. Conivaptan and tolvaptan are the two vasopressin antagonists available. Conivaptan is a nonselective vasopressin antagonist that binds to both V\textsubscript{1A} and V\textsubscript{2} receptors and is indicated for treating euvoletic or hypervolemic hyponatremia. The recommended dose of conivaptan is 20 mg administered as an intravenous infusion over 30 minutes, followed by a continuous infusion of 20 mg/day, although the treatment is limited to 2–4 days. Tolvaptan is an oral, selective vasopressin antagonist that binds specifically to V\textsubscript{2} receptors. Tolvaptan is indicated for treating symptomatic euvoletic or hypervolemic hyponatremia that has not responded to a trial of fluid restriction. The recommended starting dose of tolvaptan is 15 mg orally once daily, which can be titrated to 30 and 60 mg, depending on the serum sodium response. Both conivaptan and tolvaptan require careful monitoring of serum sodium to minimize the risk of over-correction and
osmotic demyelination. Although mechanistically, the AVP receptor antagonists serve as a targeted therapy for tumor-related SIADH, consensus guidelines do not recommend the routine use of vasopressin receptor antagonists for treating SIADH. Use of AVP receptor antagonists in the setting of malignancy is limited to case reports and case series.29,36

AVP = arginine vasopressin; cAMP = cyclic adenosine monophosphate.
SUPERIOR VENA CAVA SYNDROME

The superior vena cava (SVC) is a vessel originating from the confluence of the brachiocephalic veins and ending at the superior right atrium. Superior vena cava syndrome arises when the SVC becomes completely or partly obstructed or compressed, resulting in reduced venous drainage from the head, neck, and upper extremities to the right side of the heart. It is estimated that 15,000 cases of SVCS occur in the United States each year. Malignancies are the most common underlying factor identified in the development of SVCS; however, other factors can cause this condition. The most common malignancies associated with SVCS include lymphoma, lung cancer, breast cancer, and other mediastinal metastatic lesions. Additional nonmalignant causes of SCVS account for 35% of cases and are attributed to the frequent use of central venous catheters and thrombosis.

Diagnosis

The diagnosis of SVCS is largely clinical, and the signs and symptoms of SVCS are highly variable. The clinical presentation of each patient depends on the degree of SVC narrowing and speed of compression or obstruction. Most commonly, the onset of SVCS is slow and progressively worsens over several weeks, which allows the body to create collateral veins to provide alternative routes of venous drainage back to the right atrium. In rare cases, SCVS has been reported to develop quickly in rapidly growing tumors and thrombosis. Early signs of SVCS include facial swelling, extremity edema, distended neck and chest veins, dyspnea, non-productive cough, and hoarseness. Those with advanced symptoms of SVCS present with respiratory distress, cyanosis of the face or upper torso, engorged conjunctivae, mental status changes, coma, or seizures. In addition, patients presenting with declining cognitive function should receive a neurological evaluation to rule out brain metastases.

Imaging of the mediastinum region has a widely accepted role in the
diagnosis of SVCS. Computed tomography (CT) scan is the most useful radiographic study and should be completed with contrast material.\textsuperscript{37,39} Magnetic resonance imaging (MRI) is an acceptable alternative in patients who cannot tolerate contrast medium.\textsuperscript{37} Imaging studies can aid in identifying the underlying cause of the SVCS (i.e., external compression, thrombosis).\textsuperscript{40}

**Treatment**

Initial treatment options in managing SVCS largely depend on the severity of symptoms present on diagnosis and the underlying condition. In most cases, SVCS is not considered a medical emergency because the onset is rarely sudden and provides the body time to compensate by directing blood through the azygous system.\textsuperscript{40} Because of the slow onset of symptoms, it is considered safe and appropriate to obtain biopsies and imaging studies in an attempt to apply effective therapy. Patients who present with neurological dysfunction or airway compromise may require emergency treatment with an endovascular stent. Nonspecific measures commonly used for the primary management of SVCS aim to decrease intracranial pressure by elevating the head of the bed and administering diuretics.\textsuperscript{42} Glucocorticoids may be useful in shrinking tumors caused by lymphoma, but they offer no benefit in lung cancer.\textsuperscript{38}

Patients who warrant immediate treatment or whose chemotherapy or radiation therapy has failed may benefit from the placement of an endovascular stent that should not disrupt further diagnostic evaluations and may improve symptoms within 24–48 hours.\textsuperscript{42–44} Intravascular thrombus associated with a central venous catheter can be appropriately treated through catheter removal in conjunction with administration of an anticoagulant to minimize clot embolization.\textsuperscript{40} In addition, endovascular stent placement can be considered for thrombus associated with an indwelling catheter.\textsuperscript{43}

Cases of SVCS as a result of malignancy, newly diagnosed or preexisting, can effectively be managed by chemotherapy or radiation. Lymphoma, small cell lung cancer, and germ cell tumors are generally chemosensitive and are appropriately managed through the
administration of systemic chemotherapy. Radiation therapy is the treatment of choice for SVCS caused by non–small cell lung cancer and other metastatic solid tumors that have well-defined borders and are less chemosensitive.\textsuperscript{38,45}

\section*{NEUROLOGICAL}

\subsection*{Spinal Cord Compression}

The incidence of malignant spinal cord compression (MSCC) is estimated to be 1 in 12,700 patients with cancer, or 5%, annually.\textsuperscript{46,47} Although any metastatic or locally advanced cancer has the potential to induce MSCC, certain cancers have a stronger probability than do others.\textsuperscript{46} Malignancies of the prostate, breast, and lung have been associated with 15%–20% of MSCC cases in adults.\textsuperscript{48–50} In addition, non-Hodgkin lymphoma, multiple myeloma, and renal cell carcinoma each account for 5%–10% of cases; remaining cases are attributed to colorectal cancer, cancer of unknown primary origin, and sarcoma.\textsuperscript{46,51} Compression of the spinal cord can occur anywhere along the spine; however, most commonly, MSCC is associated with the thoracic spine (70%), followed by the lumbosacral spine (20%) and the cervical spine (10%).\textsuperscript{38} Furthermore, it is not uncommon to have involvement along the spine at several locations, which is more commonly seen in breast and prostate cancers.\textsuperscript{38}

Malignant spinal cord compression is often defined as compression of the spinal cord and/or cauda equina caused by extradural metastatic or locally advanced malignancy.\textsuperscript{38,52} Several phases are involved in the development of MSCC, the first consisting of tumor enlargement resulting in compression of the extradural space. Research suggests that the spread of metastatic disease occurs from direct arterial embolization by malignant cells.\textsuperscript{53} Continued expansion of malignant tumors resulting in worsening compression obstructs the venous plexus and leads to edema formation. Subsequent production of inflammatory cytokines increases blood flow and continues to increase the formation of edema.\textsuperscript{38} Early-stage spinal cord injury originates from edema.
formation. As the MSCC progresses, the edema induces a state of ischemia-hypoxia and, if left untreated, results in irreversible damage to the spinal cord.\(^{38}\)

**Diagnosis**

Signs and symptoms of MSCC include pain and deficits in motor, sensory, and autonomic function.\(^ {52}\) Up to 95% of patients with MSCC present with back pain at the time of diagnosis for a median of several weeks before presentation, which may precede a cancer diagnosis.\(^ {52}\) Patients describe a localized pain that progressively worsens over several weeks.\(^ {46}\) A distinguishing feature of MSCC from other types of back pain is the increase in pain when in a supine or relaxing position compared with when upright as a result of distension of the epidural venous plexus.\(^ {42}\)

Deficits in motor function are the most noticeable symptom of MSCC and are present in 60%–85% of patients at the time of diagnosis.\(^ {46,50}\) A total of two-thirds of patients diagnosed with MSCC are non-ambulatory at the time of diagnosis.\(^ {46,50}\) Early identification of motor function weakness is important because pretreatment neurological status is the most important predictor of post-treatment function.\(^ {39,46,50}\)

The prevalence of sensory deficits is estimated to occur in 40%–90% of patients with MSCC, although patients tend to be less aware of sensory deficits than of motor function deficits.\(^ {46,50}\) It is thought that sensory levels are located one to five segments below the site of spinal cord compression.\(^ {50}\)

Complications involving autonomic dysfunction include decreased anal sphincter tone, decreased perianal sensibility, and distended bladder with postvoid residual volumes greater than 150 mL.\(^ {38,50}\) Isolated incidents of any of these symptoms are not indicative of the development of MSCC. Autonomic dysfunction, specifically urinary retention, is present on diagnosis in about 50% of MSCC cases and is an unfavorable prognostic factor.\(^ {38,52}\)

Because of symptoms that are not unique to MSCC, patients should
undergo imaging studies to rule out other causes of their symptoms or to confirm a diagnosis of MSCC. The gold standard for the diagnosis of MSCC is an MRI, which provides a sensitivity of 93%, specificity of 97%, and accuracy of 95% and aids in the preparation of radiation fields. Use of an MRI for imaging lesions in one study altered radiation fields and affected treatment choices in 40% of patients. As discussed previously, involvement of more than one area of the spinal cord is common; therefore, imaging studies should include the entire spine. When an MRI is contraindicated or unavailable, CT myelography is considered an acceptable alternative.

**Treatment**

The primary treatment goals in MSCC include pain control and the preservation and/or restoration of neurological functioning. Corticosteroids are considered the first-line treatment for most patients with MSCC because they decrease edema, have tumoricidal effect in certain types of cancer, and are associated with resolution of neurological deficits. Although the most effective loading dose, maintenance dose, and treatment duration are controversial, one randomized study stratified patients to receive 96 or 16 mg of dexamethasone daily in combination with radiotherapy. Better outcomes were not associated with higher doses, but they were associated with greater rates of adverse effects. Administration practices may vary between institutions, but common corticosteroid loading and maintenance doses include high doses (dexamethasone 100 mg loading dose, followed by 96 mg daily) or moderate doses (dexamethasone 10 mg loading dose, followed by 16 mg daily).

The optimal dose and treatment regimen of radiotherapy in managing MSCC lack consistency as well. Radio-therapy should involve the malignant area of the spine as well as one or two vertebral bodies above and below the site of compression. The most commonly used radiotherapy schedule in the United States provides a total of 30 Gray in 10 fractions because higher doses have not been associated with better outcomes. Lower doses and fewer fractions could be appropriately considered in patients who have a poor prognosis or
more comorbidities.

Given recent surgical advances, patients who have a favorable performance score may benefit from decompression surgery. Those who can withstand a surgical procedure may achieve immediate decompression as well as spinal reconstruction to provide stabilization.\textsuperscript{53} A randomized trial determined that direct decompressive surgery plus radiotherapy was superior to radiotherapy alone for improving and regaining the ability to walk, increasing overall survival and functional ability, maintaining continence, and reducing opioid analgesic use.\textsuperscript{57} Weaknesses of this study include the lack of generalizability to every tumor type seen in practice and the inclusion of patients with only one area of spinal cord involvement. As a result, eligible patients should be compared with those included in this study to determine the best treatment modality for their primary tumor causing MSCC.

**SUMMARY**

As more treatment options emerge and people live longer with cancer, it is important to quickly and accurately identify the oncologic emergencies with which patients may present. Tumor lysis syndrome has the potential to result in nephrotoxicity, neurological defects, and myocardial events if no appropriate measures are taken. Hypercalcemia of malignancy occurs in up to 20% of patients with cancer and is a poor prognostic feature. Measures for treating HCM all work to decrease the serum calcium concentration; however, the underlying malignancy should be addressed to prevent recurrence. Clinical presentation of hyponatremia has a large spectrum of symptoms, and SIADH is usually the cause of cancer-related hyponatremia. Although the treatment of hyponatremia largely revolves around fluid restriction, it is important to address cancer-related treatment options. Superior vena cava syndrome can present as a gradual or rapid onset, with the former allowing sufficient time to decide how best to treat the patient. Therapies can range from removing the central venous catheter to placing an endovascular stent.
Patients with MSCC often present with pain and decreased neurological functioning. Treatment strategies are aimed at decreasing inflammation and targeting the primary tumor as quickly as possible to restore normal functioning. Early identification of oncologic emergencies with appropriate treatment has the potential to prevent the further complications and improve the patient’s quality of life.

Miscellaneous
LEARNING OBJECTIVES

1. Compare and contrast the different descriptors used to characterize body mass.
2. Describe the pharmacokinetic changes that occur with morbid obesity.
3. List the steps to take when calculating a dosing regimen for the morbidly obese patient.
4. Develop a pharmacotherapy plan for a critically ill patient who is morbidly obese.
5. Describe the pharmacokinetic changes that occur with pregnancy.
6. List the medications that should not be considered in the critically ill pregnant patient.
7. Develop a pharmacotherapy plan for a critically ill patient who is pregnant.
8. Describe the pharmacokinetic changes that occur with therapeutic plasma exchange.
9. Develop a pharmacotherapy plan for a critically ill patient who is undergoing therapeutic plasma exchange therapy.
10. Describe the pharmacokinetic changes that occur with
11. Develop a pharmacotherapy plan for a critically ill patient who is undergoing molecular adsorbent recirculating system therapy.

**INTRODUCTION**

Drug dosing in the intensive care unit (ICU) can be extremely challenging because of the pharmacokinetic variability that exists in this population compared with patients in a non-ICU setting. Even within the ICU, several special populations present unique challenges because of their pharmacokinetic differences and the relative lack of outcomes data available. This chapter is designed to address drug dosing in four such special populations: patients with extremes in size, pregnant patients, patients undergoing therapeutic plasma exchange, and
patients receiving molecular adsorbent recirculating system (MARS) therapy. Although several other special populations could be included in this chapter (e.g., renal replacement therapies, hepatic failure, extracorporeal membrane oxygenation), the reader is referred to that specific section in this book.

OBESITY

Body Composition and Size Descriptors
Body size and shape (also known as habitus) refer to physical attributes of individuals such as height, weight, and body proportions. Measurement of these attributes is termed anthropometry. Epidemiologic studies during several decades in the United States have shown a general increase in these measures as well as variability within each measure.¹⁻⁴ Data analyses from 2011 to 2012 have shown that 69% of the U.S. population are overweight, 35% are obese, and 6.4% are morbidly obese.⁵ With respect to weight, the morbidly obese population presents the greatest challenge with drug dosing because these patients are typically not well represented in pharmacokinetic studies that lead to recommended dosages in product labels. Of interest, several studies have shown an obesity paradox whereby mortality is lower in critically ill patients with extremes in body size.⁶⁻⁸ These findings may be confounded by the presence of malnutrition near the time of ICU admission.⁹

Several sophisticated methods exist to quantitatively assess fat mass, fat-free mass, and body water.¹⁰ Examples include bioelectrical impedance analysis, dual energy x-ray absorptiometry, and computerized tomography. However, these techniques are primarily used in the realm of research and are not routinely used in the clinical setting. Nevertheless, the metabolic aspects of these measurements can influence the pharmacokinetics of medications. For example, when mass is added to or lost from the body, there is a concomitant gain or loss (about 25% of that change) of lean tissue that is metabolically active.¹¹ Furthermore, there are different types of adipose tissue, and
variability in metabolic activity exists. White adipose tissue is responsible for nutrient and energy storage, but brown adipose tissue has energy-dissipating activity and is thought to be protective against body fat accumulation.\textsuperscript{12,13}

The descriptor used by the World Health Organization to characterize size is body mass index (BMI) (Table 41.1). However, BMI is not routinely used for medication dosing. Instead, when weight-based dosing is indicated, the patient’s measured or reported actual (total) body weight (TBW) or some adjustment from TBW is used. These adjustments can include ideal body weight (IBW), lean body weight (LBW), fat-free mass, or some other form of adjusted body weight (AdjBW). Adjusted body weight calculations commonly use a correction factor to add some portion of the difference between TBW and IBW to the IBW (Table 41.2). It is important to understand the differences and limitations with each weight measure because variance with the calculated dose of more than 100% can be noted. Ideal body weight is sometimes used as a surrogate for LBW and presumes drug distribution into lean (i.e., non-adipose) tissue. The most common formula used to estimate IBW was proposed by Devine and was thought to have originated from life insurance tables published in 1959 (Table 41.2).\textsuperscript{16} In fact, the proper terminology was actually “desirable” weight, which later became synonymous with “ideal” weight—the weight associated with the lowest mortality.\textsuperscript{18} Of note, IBW estimations are based on height alone; therefore, the value does not change with increasing weight. As such, it can be argued that LBW is a better representation of fat-free mass. One formula for LBW commonly cited in the literature is the James equation.\textsuperscript{19} This formula yields increasing weight estimations as a patient gains TBW, up to a point. Specifically, the estimation of LBW begins to decrease as TBW continues to increase (e.g., above 100–110 kg in average-height females and above 120–130 kg in average-height males).\textsuperscript{20} The James equation therefore tends to underestimate LBW at extremes in weight. In lieu of these limitations, an alternative formula was proposed by Janmahasatian et al.\textsuperscript{17} With this equation, LBW estimates continue to rise as body weight increases and may therefore better reflect the increase in lean tissue
that can also occur with increases in adiposity. Therefore, this formula should be used when estimating LBW or fat-free mass in clinical practice, particularly in more extreme forms of obesity. However, this formula can be cumbersome at the bedside; thus, it is recommended to use some form of automated dosing program (e.g., spreadsheet program) to avoid calculation errors. Another descriptor commonly used as an alternative is AdjBW using a “correction factor.” These formulas, which originated from pharmacokinetic experiments with aminoglycoside dosing, use a correction factor to account for some fraction of the difference between TBW and IBW. The most common correction factor in the pharmacokinetic literature is 0.4; however, a wide degree of variability has been reported, with correction factors of 0.14–0.98 for various drugs.21 Some have argued that a correction factor of 0.25 may better estimate LBW, given that there is about a 25% increase in lean tissue as fat mass is gained. However, there are no clinical trials comparing these methods.

CF = correction factor (usually = 0.4); IBW = ideal body weight (kg); TBW = total body weight (kg).

Although there may be a preferred weight measure for a particular drug, each of the aforementioned size descriptors is limited by its inability to assess the ratio of fat mass to fat-free mass. This permits assumptions about body composition that may not be entirely accurate. The importance of this is shown in the following example. Suppose a loading dose is needed for a medication in three male patients, all 40 years of age, all 70 inches tall, and all weighing 100 kg. The first patient is very muscular with very little fat mass, the second has obesity, and the third has substantial fluid retention. All would receive the same dose based on all weight descriptors (i.e., TBW, IBW, LBW, etc.), but there are clearly differences in body composition that could influence volume of distribution and/or clearance and the resultant drug concentrations.

Pharmacokinetic Considerations
The two independent pharmacokinetic parameters commonly used to describe drug disposition in the body are volume of distribution and clearance. Volume of distribution is a theoretical parameter used to describe the size of the compartment into which a drug will distribute. This is the most influential parameter when a single dose of medication is administered such as a loading dose. In general, drugs with a smaller volume of distribution tend to be hydrophilic drugs and remain in the extracellular space with little distribution into adipose tissue. Drugs with larger volumes of distribution are often more lipophilic and distribute into adipose tissue and other areas of the body.

The second pharmacokinetic factor used to describe drug disposition is clearance. Studies evaluating the impact of obesity on clearance have produced mixed results. Some studies have shown an increase in clearance, largely because of increased kidney size and blood flow, whereas others have shown no difference. One challenge related to clearance in the patient with obesity is which weight to use in formulas for estimating creatinine clearance. One study compared measured creatinine clearance with calculated estimates using the Cockcroft-Gault formula and different measures for weight (TBW, IBW, AdjBW with correction factors of 0.3 and 0.4, LBW). Total body weight overestimated true clearance by almost 2-fold, whereas IBW underestimated clearance by around 23%. Lean body weight using the formula from Janmahasatian et al. provided the most accurate estimations of measured creatinine clearance. Strengths of this study are that it included hospitalized patients as opposed to healthy volunteers, though patients admitted to an ICU were excluded.

When considering the pharmacokinetic differences that exist in patients with obesity versus nonobese patients, the concept of dose proportionality must be examined. Dose proportionality suggests that as weight increases (from standard size to a nonstandard size), pharmacokinetic parameters such as volume of distribution and clearance increase by the same ratio. For example, assume that a drug is given as a 1-mg/kg dose with a volume of distribution of 50 L and a clearance of 100 mL/minute according to studies of middle-aged adults with normal size, shape, and weight. Next, assume that the
same drug is given to a group of patients with morbid obesity who have
the same age and height but who weigh twice as much. If the resultant
volume of distribution and clearance are 100 L and 200 mL/minute, the
concept of dose proportionality will apply because a doubling in weight
is associated with a doubling in volume of distribution and clearance
and no change in volume of distribution or clearance relative to weight
(i.e., liters per kilogram or liters per hour per kilogram). In that setting,
TBW would be the most appropriate measure to use for weight-based
dosing. In contrast, if the volume of distribution and clearance do not
change in proportion to the observed differences in TBW, another
weight measure such as LBW or AdjBW using some correction factor
may better reflect the changes that occur. In general, few drugs that
are renally eliminated have characteristics of dose proportionality.

Calculating a Dose in the Patient with Morbid Obesity
Although several factors must be considered when calculating a dosing
regimen for the critically ill patient with morbid obesity, a few
overarching principles exist (Box 41.1). These factors should be
assessed in conjunction with the stepwise approach presented in the
paragraphs that follow. With that in mind, the first step is to assess the
degree of obesity in the individual patient. When dealing with mild to
moderate forms of obesity (i.e., BMI 25–35 kg/m$^2$), published dosing
recommendations are usually appropriate because these patients were
likely included in the trials that led to the dosing in the product label. As
BMI approaches and exceeds 40 kg/m$^2$ (i.e., morbid obesity), drug
dosing is more complicated because these patients were often
excluded from dosing studies or represented in such small numbers
that a meaningful conclusion cannot be drawn. In these instances, the
clinician should evaluate clinical trials with that medication conducted in
patients with morbid obesity. It is important to assess whether the
degree of obesity presented in the trials is similar to that of the
individual patient at hand, especially if dealing with more extreme forms
of obesity (i.e., BMI greater than 50 kg/m$^2$).

If clinical trials do not exist or if the patient does not fit the profile of
the patients in the clinical investigations, the clinician should search for
pharmacokinetic trials of patients with obesity and assess whether dose proportionality exists. For medications that are weight based (i.e., milligrams per kilogram of body weight), the clinician must weigh the benefits and risks of using TBW versus LBW or some correction factor AdjBW. For medications that are non–weight based (i.e., milligrams per dose), the clinician may choose to administer a dose on the higher end of the recommended dosing range. If pharmacokinetic trials specific to patients with obesity do not exist, some generalizations can be made regarding pharmacokinetic parameters. Drugs that have a small volume of distribution typically do not distribute extensively into adipose tissue. Weight-based dosing, particularly for loading doses, can be performed using LBW. Drugs with a large volume of distribution would be anticipated to require loading doses based on TBW or AdjBW, but there are exceptions to this generalization. For example, digoxin has an average volume of distribution of around 500 L but is proportional to IBW (according to the Devine equations) and not TBW.23 This is because digoxin has a high affinity for cardiac and skeletal muscle, and adipose tissue is not an active reservoir. Clinicians must therefore use caution when making assumptions based on volume of distribution, especially when it is high.

In some situations, when clinical and pharmacokinetic trials do not exist, it may be necessary to extrapolate dosing information from similar drugs (i.e., drugs in the same structural class) or consider an alternative agent. Other important factors to consider are the adverse effect profile of the medication and the method for administering and titrating to effect. For some medications (especially those with dose-dependent adverse effects), it may be preferable to use a series of smaller doses that can be rapidly titrated to effect versus a single, large loading dose or maintenance doses that may be based on TBW (even when TBW may be the preferred weight measure for dosing). This method is commonly used for sedatives and analgesics in the postoperative setting. Finally, the ability to do therapeutic drug monitoring may be considered when selecting an agent and used whenever available. This allows the clinician to rapidly assess whether pharmacokinetic and pharmacodynamic goals are being met and to
adjust the dosing regimen as necessary.

**Medication-Specific Recommendations**

**Analgesics**

Even though opioid medications are highly lipophilic compounds, LBW is the most appropriate weight measurement for dosing them. One study evaluated analgesic response with a fixed 4-mg dose of morphine and reported no significant differences between individuals who were nonobese, individuals with obesity, and individuals with morbid obesity. Similarly, studies with fentanyl have shown a nonlinear relationship between dosing requirements and TBW. Dosing regimens based on TBW could therefore lead to excessive dosing in patients with morbid obesity. Remifentanil pharmacokinetics were evaluated in one study where the volume of distribution and the clearance were more closely related to lean body mass than to TBW. A second study evaluated sufentanil and showed a linear correlation between the volume of distribution and the degree of obesity, with a prolonged half-life in patients with obesity. This suggests that TBW should be used for loading doses, but LBW or IBW for maintenance dosing.

In summary, available data analyses suggest that dosing adjustments with opioids are unnecessary in patients with obesity and that the same strategy as used in nonobese patients can be sought. Because opioid doses in adult patients are typically non-weight based, incremental doses that can be rapidly titrated to effect (similar to what is used in a recovery room setting) are recommended. In all cases, the degree of underlying pain, age of the patient, presence of ventilatory support, and likelihood that tolerance is occurring should be used to guide therapy.
Seek consistency with the weight measure that is used for weight-based dosing and for all dosing-related calculations (e.g., creatinine clearance calculations).

Use dosing calculators or computer programs to assist with calculations from complex formulas.

When evaluating the literature for data to assist with dosing, verify the weight of the actual patient in question is within the range of weights included in the clinical trial.

The degree of variability in pharmacokinetic parameters (such as volume of distribution and clearance) is much greater in critically ill patients than in the non–critically ill population.

When no outcomes data are available, clinicians should evaluate pharmacokinetic studies to assess for dose proportionality.

When there are no comparative pharmacokinetic data, the clinician must balance the risk of adverse effects using a higher dose (or dosing based on TBW) with the risk of treatment failure using lower doses (or dosing based on LBW).

In some cases, even when TBW may be the most appropriate measure for weight-based dosing, the adverse effect profile may preclude its use in favor of smaller doses that can be rapidly titrated to effect.

---

LBW = lean body weight; TBW = total body weight.

**Sedatives**

Sedation strategies that use non-benzodiazepine medications are preferred in mechanically ventilated, critically ill patients because of
their association with reduced durations of mechanical ventilation and shorter ICU lengths of stay. Propofol is the most widely used sedative because of its favorable pharmacokinetic profile, including a rapid onset and short duration of effect. Several pharmacokinetic models have been developed to evaluate propofol pharmacokinetics and pharmacodynamics in patients with morbid obesity. Servin et al. reported that both clearance and volume of distribution were correlated with TBW (r=0.76 and 0.61 for clearance and volume of distribution, respectively). Others have developed allometric models using TBW or some form of AdjBW to better characterize propofol dosing. Nevertheless, despite these data implying that TBW is the preferred weight measure for weight-based dosing, several studies have shown obesity to be an independent predictor of propofol-related adverse effects. Therefore, because of the hemodynamic concerns with large doses of propofol and the fact that propofol can rapidly be titrated to effect, either LBW or some correction factor AdjBW should be used for initial dosing calculations.

There are no data evaluating the impact of obesity on dexmedetomidine pharmacokinetics in the ICU. Pharmacokinetic studies with dexmedetomidine have shown a large volume of distribution (greater than 100 L), and one study noted clearance to be correlated with weight. Nevertheless, because of concerns with adverse effects such as bradycardia and hypotension, either LBW or AdjBW should be used for weight-based calculations, with titration to the desired level of sedation.

Benzodiazepines are highly lipophilic compounds, and marked differences in pharmacokinetic variables have been detected in individuals with obesity compared with nonobese individuals. In one study with midazolam, both volume of distribution and elimination half-life were significantly greater in the obese cohort (volume of distribution 2.66 vs. 1.74 L/kg; half-life 5.94 vs. 2.27 hours). The observed increase in half-life was presumed to be caused by the large volume of distribution because no difference was noted in total clearance (472 vs. 530 mL/minute). Therefore, LBW should be used to calculate doses for continuous infusions, but TBW can be considered for single doses
(because of increased volume of distribution). A safer approach, though, would be to use LBW or a series of smaller intravenous doses until the desired effect is achieved.

**Neuromuscular Blocking Agents**

Most neuromuscular blocking agents are polar, hydrophilic compounds, which suggests that distribution into adipose tissue is limited and that LBW is the preferred weight measure for both loading and maintenance doses. This was confirmed in several pharmacokinetic studies evaluating the neuromuscular blocking agents vecuronium, rocuronium, atracurium, and cisatracurium, where a longer duration of action was seen when doses were calculated according to TBW.\(^{39-42}\) Succinylcholine, however, should be dosed according to TBW because of the strong correlation between pseudocholinesterase activity and BMI.\(^{43}\) Furthermore, research has shown a substantial number of patients with poorer intubating conditions when either IBW or LBW was used rather than TBW.\(^{44}\)

**Anticoagulants**

Anticoagulant dosing can be particularly challenging because of the deleterious effects associated with doses that are too low and the increased risk of bleeding when doses are too high. Several studies have evaluated the pharmacokinetics of anticoagulants in obesity when used for both venous thromboembolism (VTE) prophylaxis and treatment.

**Prophylaxis**

In most hospitalized patients, the choice of an anticoagulant for VTE prophylaxis is between a low-molecular-weight heparin (LMWH) and low-dose unfractionated heparin. There is no class I evidence to provide guidance on the preferred agent, but one study of more than 24,000 bariatric surgery patients showed the adjusted rates of VTE to be lower in patients who received LMWH (0.25%) compared with those who received unfractionated heparin (0.68%).\(^{45}\) No significant difference in hemorrhage rates occurred. Other studies have evaluated
prophylactic dosing of LMWH in obesity, most of which are specific to the bariatric surgery population and not the critically ill. Overall, it appears that higher doses are necessary to achieve antifactor Xa (anti-Xa) concentrations in the recommended range, but the exact dose is less clear. Scholten et al., who conducted a pre-post study using enoxaparin 40 mg every 12 hours (compared with 30 mg every 12 hours) in bariatric surgery patients, reported significantly fewer VTE events (0.6% vs. 5.4%, p<0.01).46 This is one of the few prospective studies that used VTE events as the primary outcome measure. Other investigators have evaluated a BMI-stratified or weight-based approach. In one study, patients with a BMI of 50 kg/m² or less received enoxaparin 40 mg every 12 hours, whereas those with a BMI greater than 50 kg/m² received 60 mg every 12 hours.47 The incidence of subtherapeutic anti-Xa levels was slightly lower in the 60-mg dosing cohort (21% vs. 14%), indicating that a higher dose was required when the BMI exceeded 50 kg/m². However, supratherapeutic anti-Xa levels were somewhat higher (0% vs. 17%). A second study evaluated a BMI-stratified approach for dosing enoxaparin in bariatric surgery.48 In this study, twice-daily enoxaparin was administered in 30-mg doses for patients with a BMI less than 40 kg/m², 40 mg for BMI 41–49 kg/m², 50 mg for BMI 50–59 kg/m², and 60 mg when BMI exceeded 59 kg/m². No episodes of VTE were recorded, and 5 of 170 (2.9%) had a bleeding event (40-mg dose, n=4; 60-mg dose, n=1). Ludwig et al. evaluated a weight-based approach for dosing enoxaparin in surgical ICU patients using 0.5 mg/kg twice daily.49 The mean BMI for this cohort was 46.4 kg/m², and 30% had BMIs greater than 45 kg/m². Overall, 91% of patients had anti-Xa levels in the therapeutic range, and only one patient had minor bleeding. Finally, Bickford et al. evaluated a similar regimen (enoxaparin 0.5 mg/kg twice daily) in a cohort of trauma patients.50 Target anti-Xa levels were achieved in 86% of patients. Overall, the cumulative data suggest that higher-than-standard doses are required for the obese population. However, the specific dose requires further study. The only dosing regimen associated with outcomes data (i.e., VTE rates) is 40 mg every 12 hours, but higher doses may be necessary, particularly in patients with
more extreme forms of obesity.

No comparative trials have evaluated subcutaneous unfractionated heparin dosing in individuals with morbid obesity. One study showed heparin activity (measured by anti-Xa and anti-IIa activity) to be related to abdominal skinfold thickness. In fact, a relative decrease in anti-Xa activity of around 33% was noted when abdominal skin-fold thickness increased from 10 mm to 20 mm. Higher doses can therefore be considered.

Treatment

Several pharmacokinetic studies have evaluated weight-based dosing of LMWHs, but few include a large number of patients with more extreme forms of obesity. One retrospective study of patients with morbid obesity (BMI greater than 40 kg/m²) reported lower initial doses of enoxaparin based on TBW (0.8 mg/kg every 12 hours) but anti-Xa levels that were either at or above the recommended range in 84% of patients. A subgroup analysis from the ESSENCE (Efficacy and Safety of Subcutaneous Enoxaparin in Unstable Angina and Non-Q-Wave MI) and TIMI (Thrombolysis in Myocardial Infarction) 11B trials showed no difference in efficacy (composite of death, myocardial infarction, or urgent revascularization) or major hemorrhage between patients with and without obesity when enoxaparin was dosed according to TBW, but the average weight and BMI for the cohort with obesity were only 94 kg and 33.8 kg/m², respectively. In contrast, a second study showed that bleeding rates may be higher in patients with more extreme forms of obesity. This study used a large, national, quality improvement database in which 19,061 patients with acute coronary syndromes were stratified into four cohorts according to TBW (100 kg or less, 101–120 kg, 121–150 kg, and greater than 150 kg). Major bleeding rates followed a U-shaped pattern, being highest in patients who weighed 100 kg or less and greater than 150 kg. Of interest, 80% of patients who weighed more than 150 kg received a lower dose than recommended based on TBW (1 mg/kg). When bleeding rates were compared between patients who received recommended doses (0.95–1.05 mg/kg) and reduced doses (less than
0.95 mg/kg), recommended doses were associated with a 2.4-fold increase in bleeding. Nevertheless, published recommendations suggest that LMWHs should be dosed using TBW without a dose-capping strategy. Given the potential for bleeding, particularly when weight exceeds 150 kg, using some correction factor AdjBW with anti-Xa monitoring may be a safer approach.

In many situations, the safest strategy to obtain therapeutic anticoagulation in a patient with morbid obesity is to administer a continuous infusion of unfractionated heparin. Unfractionated heparin offers the advantage of a shorter half-life, an effect that subsides more rapidly on discontinuation and offers more efficient reversal with protamine, should a bleeding event occur. Nevertheless, issues still exist regarding unfractionated heparin dosing in obesity. Unfractionated heparin has a volume of distribution that is similar to the blood volume, thereby suggesting IBW or LBW as the most appropriate weight descriptor for dosing. However, the published nomograms commonly used in clinical practice are based on TBW. In one study, activated partial thromboplastin time (aPTT) values were significantly higher in patients with morbid obesity (BMI greater than 40 kg/m$^2$) who received initial heparin doses of 80 units/kg and 18 units/kg/hour based on TBW compared with their non-morbidly obese counterparts (BMI of 40 kg/m$^2$ or less), who received similar initial, weight-based doses. A second report described heparin dosing in a patient weighing 388 kg with suspected pulmonary embolism. This is the heaviest patient in the literature for whom heparin dosing is described. In this case report, a therapeutic aPTT was ultimately reached with a dose of 9.4 units/kg/hour based on TBW. Of interest, this translates to a dose of 18.7 units/kg/hour (a common initial dose in most nomograms) based on an AdjBW. Therefore, given the association between heparin doses using TBW and supratherapeutic aPTTs, a strategy using AdjBW with a correction factor of 0.3 or 0.4 is suggested.

**Antimicrobial Agents**

Dosing of antimicrobial agents requires careful consideration of the pharmacokinetic alterations that occur with obesity and whether these
alterations infringe on the ability to reach agent-specific pharmacodynamic goals (Table 41.3). With respect to pharmacodynamics, antibiotics are classified as either concentration- or time-dependent. With concentration-dependent antibiotics, the goal is to achieve the highest possible concentration (balancing efficacy and safety) above the minimum inhibitory concentration (MIC) for that organism. Time-dependent antibiotics, however, require maximizing the time that drug concentrations remain above the MIC. For most antibiotics, obesity is associated with an increase in both volume of distribution and clearance. These changes can lead to lower peak concentrations (important for concentration-dependent antibiotics) and prolonged periods of subtherapeutic concentrations (important for time-dependent antibiotics). The exact degree of variability depends on the specific antibiotic in question, and careful assessment for dose proportionality is required. Furthermore, the implications of this variability on clinical outcomes depend on several factors such as the pharmacodynamic characteristics of the antibiotic, the MIC of the infecting organism, the site of the infection, and the presence of host-immune factors.

**Surgical Prophylaxis**

Several studies have evaluated antimicrobial dosing in obesity in the setting of surgical prophylaxis.⁵⁹–⁶² In one study, a 2-g dose of cefazolin was compared with a 3-g dose in patients who underwent bariatric surgery.⁶⁰ Using cefazolin serum concentrations, pharmacokinetic variables were assessed, and a pharmacodynamic model was developed. In the patient cohort with a BMI greater than 50 kg/m², the time that the free (unbound) drug concentration was above the MIC (where MIC was 8 mcg/mL) was 4.1 hours for the 2-g dose and 4.8 hours for the 3-g dose. It was concluded that both regimens would provide sufficient antibiotic exposure for most surgical procedures. In contrast, Brill et al. used a microdialysis technique to compare unbound cefazolin concentrations in subcutaneous adipose tissue, together with serum concentrations, in a group of bariatric surgery patients with morbid obesity (average BMI was 47 ± 6 kg/m²)
versus nonobese controls (average BMI was 28 ± 3 kg/m$^2$). After a 2-g dose, no difference was noted in the area under the curve (AUC) with serum concentrations, but subcutaneous adipose tissue concentrations were significantly lower in patients with morbid obesity. A Monte Carlo simulation model showed serum concentrations below those required to reach pharmacodynamic goals after 180 minutes, particularly with organisms having a higher MIC. In lieu of these results, together with a relatively safe adverse effect profile, a 3-g dose is recommended. If dosing consistency is a priority (between patients with and without obesity), a 2-g dose can be administered, but measures are necessary to ensure the dose is repeated intraoperatively after 2–3 hours.

Similar results have been reported with cefoxitin. In a microdialysis study using subcutaneous adipose tissue from patients undergoing elective abdominal or pelvic surgery, cefoxitin concentrations were markedly reduced in patients with obesity. In fact, tissue penetration (measured as $\frac{AUC_{\text{tissue}}}{AUC_{\text{plasma}}}$) was only 22% of that reported in normal-weight patients, even though patients with obesity received a higher dose (2 g vs. 1 g). Suboptimal pharmacodynamics with cefoxitin have also been described in non–critically ill patients with normal body habitus. Using cefoxitin in patients with morbid obesity (at least using standard dosing regimens) can be questioned.

Treatment
Penicillins, Cephalosporins, and Carbapenems
β-Lactams are one of the more commonly prescribed classes of antimicrobials in the critically ill, and data evaluations describing their pharmacokinetics in obesity are beginning to accumulate, although they are still limited. In general, both volume of distribution and clearance are increased in patients with obesity and thereby have the potential to decrease their time above the MIC. One study evaluated β-lactam pharmacokinetics (piperacillin/tazobactam, cefepime, ceftazidime, and meropenem) in a cohort of critically ill patients with and without obesity. Overall, marked variability was noted, and a substantial number of patients both with and without obesity did not attain adequate serum concentrations with standard dosing regimens. This highlights the influence that critical illness may have on drug pharmacokinetics and the limitations with extrapolating data from non-ICU settings. A second report evaluated only piperacillin/tazobactam dosing in patients with morbid obesity admitted to a trauma/surgical ICU. In this study, pharmacodynamic goals were successfully reached (up to the susceptibility breakpoint of 16 mg/L) using a standard dose of 4.5 g every 6 hours infused over 30 minutes.
Cefepime dosing has been described in patients with morbid obesity who underwent bariatric surgery. Using patient-specific pharmacokinetic data, pharmacodynamic models were developed for two dosing scenarios: 2 g every 12 hours and 2 g every 8 hours. The time above the MIC fell below the goal of 60% when the MIC was greater than 4 mg/L for the every-12-hour regimen and greater than 8 mg/L for the every-8-hour regimen. Cefepime should therefore be administered using a dose of 2 g every 8 hours.

Most studies evaluating carbapenem pharmacokinetics in obesity were conducted in the non-ICU population, but one study assessed meropenem dosing in nine critically ill patients with morbid obesity. Meropenem volume of distribution was slightly larger than the averages reported in nonobese patients (38 L vs. 22–29 L), but clearance was similar (10.5 L/hour vs. 9.3–11.5 L/hour). Pharmacodynamic modeling showed that standard dosing (1 g every 8 hours over 30 minutes) could attain target pharmacodynamic goals when MICs were 2 or lower. A second study reported doripenem pharmacokinetics in 10 non-ICU patients with morbid obesity. In this study, obesity was associated with both higher volumes of distribution and clearance compared with those previously reported in nonobese patients. However, these changes did not lead to the inability to reach pharmacodynamic targets because standard dosing (500 mg intravenously every 8 hours over 60 minutes) was sufficient for MICs of 2 or less. Finally, ertapenem pharmacokinetics were evaluated in 30 healthy volunteers whose weight ranged from normal (i.e., BMI less than 25 kg/m$^2$) to morbidly obese (average BMI was 43 kg/m$^2$). Area under the curve was significantly lower in individuals with obesity than in those with normal weight. Standard dosing (1 g daily) failed to reach pharmacodynamic targets in any of the patients (obese and nonobese). Of interest, one study compared clinical outcomes in colorectal surgery patients who received either ertapenem or cefotetan, and surgical site infections were greater in both treatment groups when the BMI exceeded 30 kg/m$^2$ than in patients whose BMIs were below 30 kg/m$^2$ (ertapenem 27% vs. 13%; cefotetan 42% vs. 26%). In summary, it appears that standard doses of both meropenem and doripenem can be used in
patients with morbid obesity, but use of ertapenem should be reconsidered, based on its inability to reach pharmacodynamic goals and the higher incidence of clinical failure in patients with obesity.

Fluoroquinolones
Even though fluoroquinolones are one of the more commonly used classes of antimicrobials in the critically ill, data describing their dosing in obesity are limited. One study reported increases of 23% for volume of distribution and 29% for renal clearance in a cohort of healthy volunteers with obesity (vs. nonobese controls) who received ciprofloxacin. A second report described a patient weighing 226 kg who received ciprofloxacin 800 mg intravenously every 12 hours and achieved a peak serum concentration within the desired therapeutic range. In contrast, one study of healthy volunteers reported no differences in either volume of distribution or clearance after a weight-based ciprofloxacin dose of 2.85 mg/kg. Levofloxacin pharmacokinetics were described in one study that included hospitalized patients with obesity and ambulatory volunteers. In this study, wide variability occurred, but both volume of distribution (liters) and clearance (milliliters per minute) were similar to that reported in the package labeling. Dosage adjustments therefore appear to be unnecessary. Nevertheless, pharmacodynamic goals can be difficult to reach with levofloxacin, even in normal-sized individuals. Caution is warranted when using levofloxacin in patients with morbid obesity, especially when treating gram-negative organisms with an MIC of 1 or greater.

Aminoglycosides
Several studies have evaluated aminoglycosides in obesity, and both volume of distribution and clearance values tend to increase. However, there is much variability regarding the extent of that change, and it is not proportional to weight gain. One review noted an increase of 9%–58% for volume of distribution and 15%–91% for clearance in patients with obesity compared with nonobese controls. Aminoglycoside doses in patients with obesity should be determined using AdjBW with a correction factor of 0.4, recognizing that a range of correction factors
have been reported.\textsuperscript{75} Intervals are more often chosen according to the estimated half-life.

An important factor when considering an aminoglyco-side as a potential option in the morbidly obese population is whether the required dose for attaining optimal peak concentrations is within the individual clinician's range of comfort. With large-dose (e.g., 7 mg/kg AdjBW) and extended-interval (e.g., 24 hours for normal renal function) aminoglycoside dosing strategies, it is not uncommon for calculated initial doses to exceed 1 g (for gentamicin or tobramycin) in patients with morbid obesity, which could prompt the use of a dose-capping strategy. Dose capping has the potential to prolong the time to reach goal peak concentrations while waiting for concentrations to be measured/reported and could possibly affect the clinical outcome. For this reason, other appropriate antibiotics should be considered as first-line therapy for treating gram-negative infections in patients with morbid obesity.

Vancomycin
Vancomycin is one of the more challenging antibiotics to dose in obesity because of the many factors that influence its clearance beyond size and calculated creatinine clearance.\textsuperscript{76} Several studies have shown that vancomycin pharmacokinetics correlate best with TBW, which is the weight descriptor recommended in published guidelines.\textsuperscript{77,78} However, this does not imply dose proportionality, and clinicians must evaluate the specific differences identified in both volume of distribution and clearance in patients with morbid obesity. For example, Bauer et al. reported a volume of distribution of 52 L in a cohort of patients with morbid obesity (average weight 165 kg) compared with 46 L in those with normal weight (average weight 68 kg),\textsuperscript{79} with clearance values of 197 mL/minute and 77 mL/minute, respectively. In this example, the principles of dose proportionality would apply for clearance but not for volume of distribution. Blouin et al. found a volume of distribution of 43 L in patients with morbid obesity (average weight 165 kg) versus 29 L in normal-weight patients (average weight 75 kg),\textsuperscript{80} with clearance values of 188 mL/minute and 81 mL/minute, respectively. Similarly, the
concept of dose proportionality is valid for clearance but not for volume of distribution. Adane et al. evaluated vancomycin pharmacokinetic parameters in a cohort of patients with morbid obesity (median weight 148 kg) with confirmed Staphylococcus aureus infections. Population mean volumes of distribution were 0.51 L/kg based on TBW (0.76 L/kg based on AdjBW with a 0.4 correction factor), and clearance was 6.54 L/hour. Scatterplots had better correlation of volume of distribution and clearance with TBW than with AdjBW.

Several papers have linked vancomycin-induced nephrotoxicity to exposure and AUC, but nephrotoxicity may also be influenced by weight. In one study, weight in excess of 101 kg was significantly associated with nephrotoxicity (hazard ratio 3.17 [1.18–8.53], p=0.022) together with trough value and ICU residence. This could be related to more extensive vancomycin exposure because the mean trough values were only slightly higher (12.5 vs. 9.8 mg/L, p=0.03).

In summary, some disparity exists in the available pharmacokinetic data regarding the relationship between weight and volume of distribution. This would be most relevant for calculating a loading dose because volume of distribution is the primary determinant of concentration. Given the concern with dose-related adverse drug events, a conservative approach would be to use AdjBW for weight-based calculations, especially because loading doses are typically 25–30 mg/kg. However, maintenance doses and the resultant AUCs are largely influenced by clearance; therefore, TBW may be the more appropriate weight descriptor. Regardless of the weight descriptor chosen to calculate the initial regimen, therapeutic drug monitoring should be used with adjustments as necessary. Measuring two serum concentration samples with an individualized pharmacokinetic assessment may be superior to a trough-only monitoring method in these patients.

Linezolid

Linezolid is more commonly used for methicillin-resistant S. aureus in critically ill patients, but data in patients with obesity are limited. Studies have shown lower serum concentrations in patients with morbid obesity, but substantial differences in clinical cure have not been
recognized.\textsuperscript{85–87} However, one case report described failure with linezolid in a patient weighing 265 kg (BMI 82 kg/m\textsuperscript{2}). In this report, peak and trough concentrations were only 4.13 and 1.27 mcg/mL, respectively.\textsuperscript{88} Therefore, standard dosing regimens (600 mg intravenously every 12 hours) can be considered when the BMI is 50 kg/m\textsuperscript{2} or less, but caution should be used in patients with more extreme forms of obesity or with organisms having a high MIC.

Daptomycin
The daptomycin product label recommends TBW as the measure for weight-based dosing, even in patients who are obese.\textsuperscript{89} However, pharmacokinetic studies have not shown dose proportionality with parameters such as volume of distribution and clearance.\textsuperscript{90,91} Higher concentrations have been noted with daptomycin (after weight-based dosing) in patients with obesity compared with nonobese patients, which may in fact be advantageous because of concentration-dependent killing. Adverse effects, however, may be more prevalent because several studies have reported increased creatinine phosphokinase concentrations when daptomycin was dosed as milligrams per kilogram using TBW in obesity.\textsuperscript{92,93} This has prompted some to suggest consideration for LBW or some correction factor AdjBW in this population.\textsuperscript{94,95}

\textbf{CONSIDERATIONS FOR UNDERWEIGHT PATIENTS}

Few data exist to evaluate drug dosing in patients who are markedly underweight. In general, standard drug doses or doses on the lower end of the dosing range should be appropriate. One precaution, though, pertains to anticoagulant medications. Fixed doses of medications such as LMWH, when used for VTE prophylaxis, can yield concentrations more consistent with therapeutic anticoagulation than with prophylaxis. In fact, the product label for enoxaparin cites increased exposure when weight is less than 45 kg for women and 57 kg for men.\textsuperscript{96} Bleeding rates may be higher if standard doses are administered. Bleeding rates may also be higher with weight-based
dosing of anticoagulants. A large registry trial of patients with acute VTE who received either LMWH or unfractionated heparin reported bleeding rates of 8.3% and 3.9% when TBW was less than 50 kg and between 50 and 100 kg, respectively (odds ratio [95% confidence interval] 2.2 [1.2–4.0]).

This difference occurred primarily because of minor bleeding.

A second complication that can occur in underweight patients is the presence of cachexia. Cachexia is a weight-loss syndrome characterized as an involuntary weight loss of 5% or more (or a BMI less than 20 kg/m²) plus at least three of the following: decreased muscle strength, fatigue, anorexia, low fat-free mass, and/or abnormal biochemistry.

It is not synonymous with age-related muscle loss, starvation, malabsorption, or other conditions where TBW may be low. Pharmacokinetic alterations encountered with cachexia include decreased volume of distribution, altered protein binding (because of hypoalbuminemia), and reduced metabolism. Although most of these data are in the cancer and HIV populations, there are implications for medications administered in the ICU. Critical care clinicians should be cognizant of these alterations and calculate their medication regimens accordingly.

PREGNANCY

Critically ill obstetric patients present many challenges to the ICU team because of their unique physiology and specific medical disorders that occur during pregnancy and the postpartum period. The most common reasons for ICU admission are hemorrhage and hypertension, but about 20%–30% of obstetric ICU patients present with non-obstetric causes for ICU admission such as sepsis. One of the overarching considerations when caring for a pregnant woman is to consider the benefits and risks of medications for both mother and fetus. That said, the mother’s life and safety are the top priority, and medications should not be withheld because of fetal concerns. Fetal compromise is often the result of maternal decompensation. For many disease processes, the initial assessment during the acute phase
of illness is no different from that of a nonpregnant patient. For example, treatment of severe sepsis or septic shock should be consistent with the recommendations from the Surviving Sepsis Campaign guidelines.\textsuperscript{102,104} In fact, these guidelines have been endorsed by the Royal College of Obstetricians & Gynaecologists.\textsuperscript{105,106} Aggressive fluid resuscitation should be sought with early administration of broad-spectrum antimicrobial therapy. If fluids alone cannot maintain adequate tissue perfusion, vasopressor therapy with norepinephrine should be implemented. Although norepinephrine has been associated with uterine contractions and decreased uterine blood flow, its benefit on maternal resuscitation outweighs any risks.\textsuperscript{107,108}

### Pharmacokinetic Considerations
Pregnancy induces physiologic changes in virtually every organ system, which can substantially affect drug pharmacokinetics.\textsuperscript{100,101} The most significant change is the increase in blood volume, which is about 50% greater than in a nonpregnant patient.\textsuperscript{109} This results in a larger volume of distribution, particularly for hydrophilic medications or medications with a small volume of distribution. In addition, the increase in blood volume leads to a dilutional hypoalbuminemia whereby albumin concentrations can decrease by 20\%–30\%.\textsuperscript{100} Activity of the cytochrome P450 (CYP) system is increased, specifically isoenzymes CYP3A4, CYP2D6, and CYP2C9. Glomerular filtration increases by about 50\%; thus, medications that are predominantly renally eliminated require a dosage adjustment. Of interest, one report suggested that only 1.29\% of published pharmacokinetic studies provide data for pregnant women.\textsuperscript{110} Careful assessment and monitoring is necessary.

### Medication Classification in Pregnancy
Most clinicians are familiar with the categories used by the U.S. Food and Drug Administration to characterize the relative safety of medications used during pregnancy. This system consists of five categories (A, B, C, D, and X), which represent the overall ratio of
benefit-risk for use. One misconception is that these categories solely represent risk and increase proportionally from category A to X. For example, isotretinoin is commonly prescribed for acne and is labeled pregnancy category X because of its well-known association with birth defects. Phenytoin is labeled pregnancy category D because of congenital fetal malformation. The difference between the two drugs is not that one has a higher risk of fetal harm, but the benefit to be gained with its use (i.e., treatment of a life-threatening seizure vs. treatment of acne). Examples of medications that should be avoided in pregnancy (because of safer alternatives) are listed in Table 41.4.

Effective June 30, 2015, a new rule was implemented for labeling regarding pregnancy and lactation. The old categories (A, B, C, D, and X) were removed together with the subsections “pregnancy,” “labor and delivery,” and “nursing mothers.” These subsections were replaced by “pregnancy,” “lactation,” and “females and males of reproductive potential.” Under the new rule, the pregnancy subsection is more thorough and includes information regarding available registries of data (if existent), a summary of the risks, a statement regarding systemic absorption, and information to assist health care providers in making prescribing decisions about the medication (e.g., dose adjustments during pregnancy and the postpartum period, disease-associated maternal/fetal risk, maternal and fetal adverse reactions, and the effect of the drug on labor and delivery).

Medication-Specific Recommendations

Vasopressors
Most data surrounding vasopressor therapy are in the setting of blood pressure management during spinal anesthesia for cesarean delivery. Ephedrine and phenylephrine have been the two preferred medications for this indication. Historically, ephedrine had been preferred because of animal studies showing better preservation of utero-placental blood flow and concerns with the use of pure α-agonists. However, better fetal acid-base status with phenylephrine has been cited in several reports. In lieu of these data, several groups (including
the American Society of Anesthesiologists) have recommended phenylephrine as first-line therapy for spinal anesthesia-induced hypotension except in the setting of maternal bradycardia, where ephedrine may be preferred.\textsuperscript{116–119}

For the treatment of severe sepsis or shock, the choice of a specific vasopressor should be no different from in a nonpregnant patient. Restoring maternal perfusion pressure is of greatest importance and should override concerns for uterine vasoconstriction. Norepinephrine is therefore the agent of choice. If hypotension persists despite norepinephrine, second-line agents include epinephrine and vasopressin. Data analyses describing these agents in pregnancy are sparse. Epinephrine crosses the placenta and can inhibit contractions. Case reports have described the use of epinephrine in the setting of anaphylaxis during pregnancy. In one report, an epinephrine infusion was administered for 3.5 hours, and no fetal adverse effects were reported.

**Antimicrobial Therapy**

Early, appropriate antimicrobial therapy is crucial in the care of the critically ill, infected patient. Similar to therapy for nonpregnant patients, broad-spectrum therapy should be implemented as soon as possible. Empiric antibiotic selection should address safety to the infant, especially during the first trimester when major organogenesis takes place. However, little safety information is available for many of the newer anti-infective agents—those commonly considered for

empiric therapy in the ICU. Antibiotics such as β-lactams and macrolides have substantial data, and their use in pregnancy is generally well accepted. One large population-based, multisite, case-control study of more than 18,000 participants confirmed the safety of penicillins, cephalosporins, and macrolides, but sulfonamides and nitrofurantoin were associated with birth defects. Tetracyclines readily cross the placenta and, when used beyond the second trimester, bind calcium and cause permanent discoloration of teeth.

Fluoroquinolones are often avoided during pregnancy because of concerns with abnormal fetal cartilage development. An additional concern pertains to their mechanism of action (inhibition of DNA synthesis) and theoretical mutagenic and carcinogenic potential. These concerns originate from animal models with doses that are substantially higher than those used in the clinical arena. In humans, most studies have not shown an association with fluoroquinolones and fetal harm. Ciprofloxacin has been the most extensively studied. Therefore, although routine use of fluoroquinolones is not recommended, they can be considered when multidrug-resistant organisms are encountered.

Vancomycin is often considered for resistant gram-positive infections, but there is little information regarding its transplacental passage to the fetus. One study measured maternal and cord blood vancomycin levels at delivery after three different dosing regimens: 1 g every 12 hours, 15 mg/kg every 12 hours, and 20 mg/kg every 8 hours. Maternal and cord blood vancomycin concentrations were therapeutic in 32% and 9% with a 1-g dose every 12 hours, 50% and 33% with a 15-mg/kg dose every 12 hours, and 83% and 83% with a 20-mg/kg dose every 8 hours. No adverse effects were noted. These data analyses show significant passage of vancomycin to the fetus, but higher doses are required to reach therapeutic levels. Although vancomycin use is generally considered safe, therapeutic drug monitoring should be used.

The treatment of fungal infections in obstetric patients can be challenging because of the limited therapeutic options and the high morbidity and mortality associated with these infections. Fluconazole is widely considered for empiric therapy; however, several reports have
shown significant teratogenic risk, particularly with doses used to treat systemic infections (i.e., greater than 300 mg/day).\textsuperscript{127} Because voriconazole has been shown to be teratogenic in animal studies, it should not be considered. Similarly, the echinocandins have been studied in animal models, and teratogenic effects were recognized. There are no data in humans. Amphotericin B is the safest antifungal drug in pregnancy and considered the agent of choice. Although nephrotoxicity is an important limitation, its incidence is similar to that reported in nonpregnant patients.\textsuperscript{127} Liposomal amphotericin B can also be considered safe in pregnancy, but limited data exist with other lipidic derivatives. These products should only be considered when other polyenes are unavailable.

**Antihypertensive Medications**

Various antihypertensive agents can be considered to manage hypertension during pregnancy, but this discussion will focus on managing acute hypertensive crises in critically ill pregnant women. Intravenous hydralazine and labetalol have long been considered first-line agents because of their favorable adverse effect profile and extensive clinical experience in the critical care setting.\textsuperscript{128} Several groups, including the European Society of Cardiology, have recommended labetalol over hydralazine in pregnant patients.\textsuperscript{129,130} In fact, hydralazine is no longer listed as a first-line option because of concerns with more perinatal adverse effects. In one meta-analysis, hydralazine was associated with several adverse outcomes compared with alternative therapy (e.g., labetalol and nifedipine), including more maternal hypotension, placental abruption, adverse effects on fetal heart rate, cesarean section, maternal oliguria, and low Apgar scores.\textsuperscript{131}

The calcium channel blockers nifedipine and nicardipine are potential options, and both are safe and effective during pregnancy.\textsuperscript{132,133} In fact, nifedipine is listed as either a first- or a second-line agent, according to many guideline groups.\textsuperscript{128,130} Nifedipine should be administered orally (vs. sublingually); thus, administration in the critically ill patient may not be possible. Of note, pregnant patients
often receive concomitant magnesium therapy, and isolated reports of profound hypotension or neuromuscular blockade with nifedipine exist.\textsuperscript{133}

Several antihypertensive agents should be avoided. Agents that act on the renin-angiotensin system (e.g., angiotensin-converting enzyme [ACE] inhibitors, angiotensin II receptor blockers) are contraindicated because of increased fetal mortality and morbidity, including oligohydramnios, renal dysgenesis calvarial hypoplasia, and fetal growth restriction.\textsuperscript{133} These agents should not be used. Esmolol has the potential to cause fetal bradycardia, and loop diuretics are controversial because of theoretical concerns for reduced plasma volume. Sodium nitroprusside should be reserved for severe, life-threatening emergencies when other agents have failed because of its potential for cyanide and thiocyanate toxicity for both mother and fetus.

**Sedatives and Analgesics**

Data describing sedative and analgesic use specific to pregnancy are limited, but in general, recommendations from evidence-based guidelines should apply.\textsuperscript{134} For example, validated sedation scoring systems should be used, and light levels of sedation should be maintained. Non-benzodiazepine medications are preferred to benzodiazepines because of their association with shorter lengths of ICU stay. Propofol is the most commonly used regimen in the ICU, and its use has been described in the operating room during cesarean sections. Overall, propofol rapidly crosses the placenta but seems to have no major neonatal adverse effects.\textsuperscript{135–138} Reports characterizing the safety of propofol for longer-term sedation are limited. Case reports have described propofol use ranging from 10 to 48 hours.\textsuperscript{139–141} Although significant teratogenic events were not evident, neonatal respiratory depression (postdelivery) can occur.

Dexmedetomidine is a second, non-benzodiazepine option commonly considered in the ICU, but no studies describe its use in critically ill, pregnant women. Limited experiences with dexmedetomidine near the time of cesarean section have resulted in the delivery of healthy infants.\textsuperscript{142,143} Fetal bradycardia has not been reported, but more
rigorous evaluation is necessary, particularly with higher doses of dexmedetomidine. Dexmedetomidine may increase the frequency of uterine contraction, which may preclude its use in some pregnant ICU patients.

Studies conducted in the 1970s suggested that benzodiazepines contribute to malformations such as facial clefts when used during the first trimester, but later studies (that were better controlled) have refuted this association. However, benzodiazepines do readily cross the placenta; therefore, neonatal respiratory depression may occur if used before delivery. High doses of intravenous lorazepam may lead to propylene glycol toxicity, given that its clearance is reduced in neonates. Nevertheless, as with all medications used in the ICU during pregnancy, risk-benefit must be assessed, and therapy should not be withheld if necessary (e.g., treatment of status).

Data with opioid analgesics during pregnancy in the ICU setting are limited, with most data in reference to maternal illicit substance abuse or opioid dependency. In general, several reports have shown that short-term use of morphine or fentanyl is considered safe. As with all opioids, though, respiratory depression can occur with higher doses or more prolonged use near the end of pregnancy. Overall, the general principles of pain management used in nonpregnant patients can be applied to pregnant ICU patients. These include using validated pain scales, not relying on vital signs alone to assess pain, and avoiding morphine in renal failure.

**Anticoagulants**

Pregnancy is associated with a hypercoagulable state that is caused by a combination of physical and hormonal factors, together with changes in the balance of procoagulant versus anticoagulant factors. Critically ill pregnant patients should receive VTE prophylaxis with either LMWH or unfractionated heparin. Neither crosses the placenta, and both are safe. Low-molecular-weight heparin may be preferred to unfractionated heparin because of its increased bioavailability and lower risk of maternal osteoporosis and heparin-induced thrombocytopenia. Dosing recommendations for
LMWH are similar to those recommended in nonpregnant patients (e.g., enoxaparin 40 mg subcutaneously daily). In some cases, though, twice-daily dosing may be necessary because of changes in renal excretion and protein binding. With unfractionated heparin, higher doses have been recommended by the American College of Obstetricians and Gynecologists: 5,000–7,500 units subcutaneously during the first trimester, 7,500–10,000 units subcutaneously during the second trimester, and 10,000 units subcutaneously during the third trimester, each every 12 hours. Of note, multidose vials of both LMWH and unfractionated heparin contain benzyl alcohol, which has been reported to cause gasping syndrome in neonates. Either preservative-free formulations or single-dose syringes are advised.

For treatment of acute VTE, either LMWH or unfractionated heparin is acceptable. Unfractionated heparin may be preferable because of its rapid onset and the ability to make frequent dosing adjustments. Inadequate anti-Xa levels have occurred with standard weight-based dosing of LMWH, which is worrisome in the setting of pulmonary embolism. If LMWH is chosen for initial therapy, twice-daily dosing should be considered. Warfarin, which has well-known fetal teratogenic effects, should not be used.

For patients with heparin-induced thrombocytopenia, either argatroban or fondaparinux can be considered. No fetal adverse effects have been reported with these agents in case reports.

**Medications for Postpartum Hemorrhage**

Postpartum hemorrhage is an obstetric emergency and one of the most common causes of maternal morbidity and mortality. Oxytocin is widely regarded as the drug of choice and works by inducing fast and long-acting contractions of the myometrium. After intravenous administration, uterine contractions have been reported within 1 minute. Administration methods (bolus vs. infusion) vary depending on the organization, but rapid administration may lead to peripheral vasodilation, hypotension, and an increase in cardiac output. As such, the American College of Obstetricians and Gynecologists recommends 10–40 units in 1 L of normal saline or...
lactated Ringer solution administered by continuous infusion.\textsuperscript{161}

If oxytocin is ineffective, ergot alkaloids (e.g., methylergonovine) are second line. These agents, which produce strong $\alpha$-adrenergic stimulation, are contraindicated in patients with hypertension, preeclampsia, or a history of myocardial infarction. An alternative to ergot alkaloids is carboprost, a prostaglandin analog. Because carboprost causes bronchospasm, it should not be used in patients with asthma or respiratory insufficiency.

Other agents that have recently been considered include recombinant factor VII and tranexamic acid. Data analyses assessing the efficacy of recombinant factor VII are primarily through case reports, case series, and registry data; there are no randomized controlled trials.\textsuperscript{162–166} One systematic review reported that recombinant factor VII was effective in stopping or reducing bleeding in 85\% of cases.\textsuperscript{164} Collectively, the most common dose was about 80–90 mcg/kg.

There is one randomized controlled trial evaluating the benefit of tranexamic acid in 144 women with post-partum hemorrhage.\textsuperscript{167} Women with blood loss exceeding 800 mL after vaginal delivery were randomized to receive tranexamic acid (4-g load over 1 hour, followed by 1 g/hour for 6 hours) or not. Blood loss at 6 hours post-enrollment was lower with tranexamic acid (median 173 vs. 221 mL, $p=0.041$), as was duration of bleeding and progression to severe hemorrhage. A second trial is ongoing that is anticipated to enroll 20,000 women.\textsuperscript{168} Of note, this trial will use a lower dose: 1 g followed by an additional 1 g if bleeding continues.

In summary, both recombinant factor VII and tranexamic acid could be useful therapies for postpartum hemorrhage; however, the current data are not robust enough to recommend them as early options. These agents can be considered when bleeding fails to resolve after traditional therapies. Further studies are needed to establish the safest and most cost-effective dose for each therapy.

---

**THERAPEUTIC PLASMA EXCHANGE**
Therapeutic plasma exchange or plasmapheresis is an extra-corporeal procedure wherein plasma is separated from the cellular components of blood and all solutes in plasma are removed. To maintain normal plasma volume, replacement solutions, which are typically albumin or fresh frozen plasma, are infused. By removing and discarding plasma, any medication or solute present in plasma is thereby lost. In the ICU, therapeutic plasma exchange may be used to treat a vast array of disorders such as thrombocytopenic purpura, myasthenia gravis, Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy, Goodpasture syndrome, rapidly progressive glomerulonephritis, and acute antibody-mediated renal allograft rejection.\textsuperscript{169,170}

Elimination through plasma exchange is a passive process that follows linear kinetics.\textsuperscript{171} A single exchange of 1 plasma volume will remove around 63% of all solutes, whereas an exchange of 1.5 times the plasma volume will remove around 78%.\textsuperscript{172} In general, a drug is more likely to be removed if it has a small volume of distribution (i.e., less than 0.2 L/kg) or a high degree of protein binding (i.e., greater than 80%).\textsuperscript{169} This differs from renal replacement therapies, where drugs with high protein binding are not effectively removed. One of the most influential factors, even more important than drug pharmacokinetics, is the time between dose administration and therapeutic plasma exchange initiation. Several studies have shown a strong correlation of drug removal when therapeutic plasma exchange was initiated shortly after dose administration.\textsuperscript{169,173} In fact, for some drugs—even those with a small volume of distribution—removal can be minimized by allowing for an adequate distribution time before initiating therapeutic plasma exchange.\textsuperscript{174} Distribution half-life can therefore be an important parameter to assess in these instances. Exchanges at the end of a dosing interval will lead to a smaller loss of drug than exchanges occurring just after a dose.

Agent-Specific Recommendations
Several pharmacokinetic studies have evaluated the effect of therapeutic plasma exchange on drug removal. Most of the available
data are not with medications commonly used in the ICU. For a review of these medications, the reader is referred elsewhere.\textsuperscript{169,171,175}

**Cephalosporins**

Several papers have described cephalosporin dosing in patients undergoing therapeutic plasma exchange.\textsuperscript{174,176-178} One report described cefepime removal after a single 2-g dose administered over 30 minutes and given 2 hours before the plasma exchange.\textsuperscript{174} Cefepime has a volume of distribution of around 0.2–0.3 L/kg, and its degree of protein binding is less than 20%.\textsuperscript{173} Despite a low volume of distribution, the amount of drug removed was only about 4%, indicating that supplemental doses are not required, provided the drug is administered at least 2 hours before plasma exchange.

The pharmacokinetic profile of ceftazidime is similar to that of cefepime, with a volume of distribution of 0.23 L/kg and protein binding of less than 20%.\textsuperscript{173} In one report, a single dose of ceftazidime 2 g was administered 15–120 minutes before plasma exchange.\textsuperscript{177} The amount of drug removal ranged from 2% to 9%, with greater extraction occurring with shorter intervals between drug administration and the procedure. It is therefore recommended to administer ceftazidime at least 2 hours before therapeutic plasma exchange.\textsuperscript{173}

Ceftriaxone has a small volume of distribution (0.1–0.2 L/kg), but unlike cefepime or ceftazidime, it is highly protein bound (90%–95%).\textsuperscript{173} One study assessed ceftriaxone concentrations when administered immediately and 6 hours before plasma exchange.\textsuperscript{178} Drug removal was greater when ceftriaxone was given immediately before the exchange (23% mg vs. 17%). A second study compared ceftriaxone concentrations after a 2-g dose administered 3 hours versus 15 hours before a plasma exchange.\textsuperscript{176} The fraction of drug removed was significantly greater with early administration (12.7% vs. 5.7%, \(p<0.05\)). Ceftriaxone should therefore be administered at least 15 hours before therapeutic plasma exchange.

**Vancomycin**

Few reports describe the impact of vancomycin removal after
therapeutic plasma exchange. The results have been inconsistent, with two reports showing minimal removal (less than 10%) and three reports showing considerable removal (i.e., up to 49%). This disparity could be a result of the timing of the dose relative to the plasma exchange because little information was provided in this respect. Given these results, administering vancomycin after therapeutic exchange seems reasonable. Therapeutic drug monitoring should be used accordingly.

Tobramycin
Data regarding the influence of therapeutic plasma exchange on tobramycin removal are limited to four patients. In these cases, the fraction of drug eliminated was only 4.3%–10.9%, but serum concentrations were markedly reduced. It is unclear whether this was secondary to the plasma exchange procedure or to endogenous aminoglycoside clearance. Nevertheless, administering tobramycin after therapeutic plasma exchange or at least 2 half-lives before the procedure is appropriate.

Digoxin
Digoxin has an extremely large volume of distribution (5–8 L/kg), and after the distribution phase, less than 1% remains in the plasma. Analyses of case reports have shown that only 1%–2% of digoxin is removed after a single plasma exchange. Therapeutic plasma exchange is therefore anticipated to have minimal influence on digoxin removal, provided it is done post-distribution.

Phenytoin
Phenytoin has a volume of distribution of about 0.65 L/kg in patients without kidney disease and is highly protein bound (90%). Theoretically, plasma exchange should have a marked influence on its kinetics; however, analyses of case report data show otherwise. Most data analyses show that only about 3%–5% of phenytoin total body stores were removed after a plasma exchange. The largest documented
removal of phenytoin was from a report wherein 10% of total body stores of phenytoin were removed, and plasma concentrations were reduced by 3.2 mcg/mL. Clinicians should use therapeutic drug monitoring to modify the dosing regimen as needed.

MOLECULAR ADSORBENT RECIRCULATING SYSTEM

Liver failure is associated with the accumulation of several toxic metabolites, many of which are highly bound to albumin. Molecular adsorbent recirculating system (MARS) therapy is a liver support system that removes protein-bound and water-soluble toxins through albumin dialysis. Molecular adsorbent recirculating system therapy is used in conjunction with continuous renal replacement therapy wherein blood is pumped through a specialized high-flux filter, and protein-bound and water-soluble substances pass through the membrane into the albumin-enriched dialysate (Figure 41.1). The albumin dialysate passes through a low-flux dialysis filter (against a bicarbonate-based dialysate) to remove water-soluble substances and then through two adsorption columns (one with uncoated charcoal and the second with an anion exchanger resin adsorber) to remove albumin-bound toxins. The regenerated albumin solution can then bind new toxins from the blood.

Drug dosing in patients receiving MARS therapy is complex because clinicians have to account for not only the drug removal with the MARS system itself, but also the clearance provided by the renal replacement therapy. It can be anticipated that drugs with both high and low degrees of protein binding will be removed. Few data describe the effect of MARS therapy on drug removal. One case report described the impact of MARS therapy on teicoplanin, a large glycopeptide (molecular weight 1,500–1,900 Da) that is about 90% protein bound. In this report, teicoplanin concentrations decreased by 73% after the first cycle of MARS therapy and 84% after the second cycle, with the duration of MARS therapy at 9 hours and 16 hours, respectively, and most drug removal occurring during the first 4 hours. A second report described moxifloxacin and meropenem removal using an in vitro
The concentration for both medications decreased by 50% within 60 minutes post-MARS initiation. Drug removal was recognized with each component of MARS (i.e., the MARS flux dialyzer, the low-flux dialyzer, the charcoal column, and the anion exchanger) for both medications. Piperacillin/tazobactam pharmacokinetics were described in one patient receiving MARS for acetaminophen-induced liver failure. After administering a single dose of 4.5 g over 3 hours (with concomitant MARS therapy), piperacillin concentrations decreased from 173 mcg/mL to 116 mcg/mL, a decrease of around 33%. In fact, the calculated half-life was 3.7-fold shorter than that previously reported with CVVHD (continuous venovenous hemodialysis) alone, indicating additional drug removal by MARS.

**Figure 41.1** Molecular adsorbent recirculating system (MARS) therapy.

**CONCLUSION**
There are variable degrees of evidence to guide clinicians with drug doses in special populations. For many of these populations, though, the data are limited to case reports or small case series. Clinicians must appreciate the pharmacokinetic variability that exists and base decisions after a careful assessment of risk-benefit. Medication regimens should be individualized and a “one-size-fits-all” approach avoided. Therapeutic drug monitoring should be used whenever applicable.

LEARNING OBJECTIVES

1. Describe the different types of burn injury and classify its severity based on size and depth and the associated morbidity and mortality with each class.

2. Develop a plan for fluid resuscitation in a burn injury patient while weighing the risks and benefits of a plan that includes crystalloids, colloids, hypertonic saline, and/or ascorbic acid.

3. Discuss the importance of managing the burn injury in the emergent setting, including the assessment and treatment of inhalation injury and cyanide toxicity.

4. Compare the nonpharmacologic and pharmacologic options for metabolic modulation in burn injury, including nutrition support, early surgical excision, oxandrolone, and propranolol.

5. Formulate a strategy to prevent and treat complications that may arise in the burn injury patient, including sepsis, glycemic control, and venous thromboembolism.

ABBREVIATIONS IN THIS CHAPTER

ABA American Burn Association
INTRODUCTION

Each year, over 450,000 individuals suffer a burn injury that requires treatment, with over 40,000 of those requiring admission to the hospital. Burn injury can affect all ages and can be caused from a variety of mechanisms, including flames, hot liquids, and chemicals. The treatment of burns has evolved over the years with advancements in fluid resuscitation, metabolic modulation, and management of complications, leading to increased survival. The critical care pharmacist can play an important role in the management of the burn injury patient by optimizing the patient’s care through recommendations on fluid resuscitation, pharmacologic metabolic modulation, and using pharmacokinetic and pharmacodynamic parameters to optimize drug therapy. The key to successful outcomes in burn injury patients are driven by a multidisciplinary team, and the American Burn Association (ABA) officially recognizes the importance of having a critically care–trained pharmacist as a member, making it a requirement for verification as a certified burn center.

EPIDEMIOLOGY OF BURN INJURY

Burn injury is defined by damage to the skin and underlying tissues caused by exposure to energy sources, including heat, chemicals, electricity, and radiation. The most common cause of burn injury is cutaneous damage from thermal energy exposure to fire or flame (43% of injuries), hot liquids (34% of injuries), or hot objects (4% of injuries).
Contact with chemicals, electricity, radiation, or other causes accounts for 14% of burn injuries. In children younger than 5 years, scald injury and contact with hot objects are more prevalent than in adults. Similar to general trauma injuries, males have a higher incidence of burn injury than do females. This trend is observed across all age groups except among patients 80 years and older. Most burn injuries occur in adults, and children younger than 16 years account for about 29% of burn-related injuries.

Although burn injury is still fairly common, associated survival has drastically increased during the past decades, with the 2004–2013 average survival rate of 96.7%. In the past decade, mortality rates have decreased significantly from 3.4% to 2.7% for males and from 4.6% to 3.3% for females, and the average hospital length of stay has decreased by 11%. Although this improvement in outcomes cannot be attributed to a single intervention, potential changes include a continued focus on burn management within specialized burn centers, advances in fluid resuscitation, early debridement and grafting, and general progress in critical care and nutritional support.

REVIEW OF NORMAL SKIN STRUCTURE AND FUNCTION

The skin serves many functions, including protection from traumatic injury and infection, sensory perception, thermoregulation, and regulation of fluid homeostasis. Understanding the normal structure and functions of the skin is vital because having this understanding can aid in describing both burn severity and the expected complications.

Normal skin structure contains two layers: the epidermis and the dermis. The epidermis serves as a protective, mechanical barrier from the environment, and the dermal layer supports the epidermis. Unlike the epidermis, which has no blood vessels or other structures, the dermis contains blood vessels, connective tissues (i.e., collagen and elastic fibers), nerve endings, fibroblasts, mast cells, lymphatics, and epidermal appendages (i.e., sebaceous glands, sweat glands, apocrine glands, mammary glands, and hair follicles). The epidermal
appendages within the dermal layer are responsible for re-
epithelialization of the epidermis and are therefore essential for wound healing in burn injury.

**METABOLIC CHANGES IN BURN INJURY**

Critical illness is known to result in a severe stress response that is heightened in both severity and duration in patients with severe burn injury. The threshold defining severe burn injury, as well as the associated pathophysiologic changes, varies by age and is about 30% of the total body surface area (TBSA) burned in children (0–18 years of age), 20% in adults (18–65 years of age), and 15% in older adults (older than 65 years). In patients with major burn injury, this stress response consists of an early (ebb) phase and a late (flow) phase. During the first 48 hours after burn injury, the ebb phase is characterized by a massive cytokine-mediated inflammatory response and a concomitantly reduced cardiac output that both contribute to hypoperfusion and hemodynamic instability. In addition, intravascular volume losses occur during this early phase through several avenues. An osmotically driven fluid shift occurs because of an intracellular shift of sodium through sodium-ATPase transmembrane pump disturbances. Histamine released from mast cells within the injured area also damages the integrity of the endothelial junctions within the capillary bed, resulting in increased capillary permeability and significant third spacing. These relative volume losses are further intensified by insensible fluid loss through the burn wound. Early studies found a 26% reduction in plasma volume in animal models with 30% TBSA burns 18 hours after injury. The rate of volume loss peaks within the first 8–12 hours after injury and slows significantly in the following 12 hours.

The late, or flow, phase typically begins after fluid resuscitation and initial stabilization is achieved. The hypermetabolic and hyperdynamic flow phase is defined by an imbalance of catabolism and anabolism, hyperglycemia, significant proteolysis, and impaired protein synthesis. Sustained increases in catecholamines accompanied by reduced
growth hormone and testosterone concentrations contribute to a hypermetabolic state in which resting energy expenditure (REE) can reach up to 2 times normal rates.\textsuperscript{6,7,10,11} Significant abnormalities occur with respect to protein and lipid catabolism, resulting in nitrogen losses, lean muscle wasting, and impaired wound healing. Increased glucagon release and GLUT-4 glucose transporter–mediated insulin resistance also contribute to significant hyperglycemia in the flow phase.\textsuperscript{12-14} Most aspects of the flow phase peak within the first month after injury, with some hypermetabolic-associated changes, such as the increased resting metabolic rate and hyperglycemia, persisting for years.\textsuperscript{12,13}

**INITIAL CARE IN BURN INJURY**

**Assessment of Burn Severity**
Accurate assessment of the severity of burn injury is crucial in determining treatment plans, including calculating fluid volumes recommended for resuscitation, transfer to an ABA verified burn center (Box 42.1) and operative needs. The rule of nines is a common and simple method for assessing burn size (Figure 42.1).\textsuperscript{15} Although this method has been validated, it has been attributed to overestimation of burn size.\textsuperscript{16} The Lund and Browder chart with a definite breakdown of body areas is associated with increased predictive accuracy (Figure 42.1). Computerized programs that incorporate three-dimensional skin structure into burn size calculations have been introduced in the past decade in an attempt to further improve accuracy and assist in documentation (i.e., Sage II, 3D Burn Vision, and BurnCase 3D).\textsuperscript{16} Regardless of the method used to determine burn size, first-degree (also known as [aka] superficial) burns are not included in the TBSA burned.

Like in assessing burn size, determining burn depth is key in determining whether surgical excision with skin grafting is required. Burn wound depth is defined as superficial, partial, or full thickness according to the degree of involvement of the epidermis and dermis. Injury limited to the epidermal layer is considered superficial (aka first degree), whereas extension into the dermis is associated with partial
thickness injury (aka second degree) (see Table 42.1). The extent of the dermal layer involved will allow for further description of partial thickness injury as either superficial or deep. Damage limited to the papillary dermis, as observed in superficial partial thickness burn injury, can heal without intervention within 2 weeks. However, injury to the basal membrane of the dermal layer associated with deep partial thickness burns precludes wound healing without surgical excision and grafting. Burn injury extending into the entire epidermis and dermis is considered a full thickness wound (aka third degree). Without surgical intervention, deep partial thickness and full thickness burn wounds will have dysfunctional spontaneous healing involving granulation, contraction, and re-epithelialization from the wound margins, which can result in significant scarring or development of a non-healing chronic wound. Therefore, surgical excision of the burn wound with autologous skin grafting is the optimal wound care plan in most cases for both deep partial thickness and full thickness burn injuries.

Box 42.1. ABA Burn Center Referral Criteria

Burn injuries that should be referred to a burn center include:
1. Partial thickness burns greater than 10% TBSA
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Full thickness burns in any age group
4. Electrical burns including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with preexisting comorbidities that could complicate management, prolong recovery, or affect mortality
8. Any patient with burns and concomitant trauma in which the burn injury poses the greatest risk of morbidity or mortality.
If the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before transfer to a burn center.

9. Pediatric burn patients in hospitals without qualified personnel or equipment for the care of children

10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention

TBSA = total body surface area.

(A) Rule of "nines"
(B) Lund-Browder diagram for estimating extent of burns

Risk Factors for Mortality
The Baux formula, which calculated mortality risk according to age plus TBSA injured, was the first predictive formula used to determine prognosis.\(^3\) Previously mentioned improvements in burn care leading to better outcomes now limit the accuracy of the Baux formula, and use for prognostication should be done with caution. A systematic review of 13 studies identified three predictors of mortality in adults with burn injury: age, burn size, and lower airway inhalation injury.\(^{17,18}\) Burn depth, female sex, comorbidities, and burn injury complicated by pneumonia may also increase the risk of mortality in adult patients with burn injury. Despite the significant limitations of the Baux formula, no single predictive formula has been accepted in its place as a gold standard.\(^{17-19}\) Among pediatric burn injury, the strongest predictor of outcome is age younger than 4 years.\(^{20-23}\) After adjusting for sex, burn size, inhalation injury, and burn etiology, a study of more than 12,000 pediatric burn admissions found that mortality risk was 2.7-fold higher for children 0–1.9 years of age and 2-fold higher for children 2–3.9 years of age than for children 4 years and older. However, children are also more likely to survive even massive burns, based on estimated lethal TBSA for 50% mortality of greater than 60% regardless of age group or burn etiology, and characteristics of burn injury may not be predictive of outcome among the pediatric burn population.\(^{23}\)

Fluid Resuscitation
During the early ebb phase, the goal of initial fluid resuscitation is adequate organ and tissue perfusion. Delayed or inadequate resuscitation can ultimately lead to the development of acute renal failure, progression of burn wound necrosis, multiorgan failure, burn shock, and increased risk of death.\(^{24,25}\) Because of the large volumes required for resuscitation associated with severe burn injury, a careful balance is required to avoid both under- and over-resuscitation. In most
developed countries, under-resuscitation after hospital admission is uncommon because standard calculations such as the Parkland formula are used to determine resuscitative volumes.

As in most areas of critical care, there is significant controversy regarding the optimal fluid, or fluid combination, to use for resuscitation in burn injury. Significant institutional variances exist in both formula and fluid type (e.g., crystalloid, colloid, plasma, starch, or combination) used for resuscitation because data are currently limited to support a goal standard. Although there is no standard for type of fluid or formula to use in calculating the volume needed, the most commonly used formula in the United States is the Parkland formula. This formula, a crystalloid-based resuscitation model using Ringer lactate solution, is recognized by the American Burn Association (ABA) as the “consensus formula.” First developed in 1968 by Baxter and Shires, the current Parkland formula consists of 4 mL/% TBSA burned per kilogram of Ringer lactate solution for resuscitation, with half of this volume administered in the first 8 hours from the time of injury, and the remaining volume infused over the following 16 hours. Despite the widespread use of the Parkland formula, there are few data in humans to support its use. Other examples of crystalloid-based burn fluid resuscitation formulas are included in Tables 42.2 and 42.3.

Debate regarding the ideal crystalloid for burn resuscitation has ensued with a focus surrounding the role of balanced solutions. Although most studies have evaluated Ringer lactate solution, Gille and colleagues compared resuscitation using Ringer lactate and Ringer acetate solution in 40 patients with severe burn injury ranging from 20% to 70% TBSA burned. Ringer acetate has components similar to those of Ringer lactate solution with the replacement of 27 mmol/L acetate for the 28 mmol/L of lactate found in Ringer lactate solution. The infusion rate for resuscitative fluids was based on the Parkland formula for all patients and was titrated to maintain a urine output of 0.5–1 mL/kg/hour. All patients received 20% albumin infusion after 12 hours to maintain serum albumin concentrations above 2 g/dL. Patients who received Ringer acetate and Ringer lactate solutions received similar median 24-hour resuscitative fluid volume (5,625 [25–75%
interquartile range 8,450 vs. 4,900 [5,550 mL, p=0.456], and volumes administered throughout admission were similar between groups. Although patients in both groups had similar baseline burn severity and sequential organ failure assessment (SOFA) scores, those who received Ringer acetate had significant improvement in SOFA scores beginning on days 3–6 of admission. Ringer acetate was also associated with significant reductions in lactate concentrations on days 1–5 of admission. Additional clinical benefits included decreased hospital length of stay and duration of mechanical ventilation. However, the benefits observed with Ringer acetate failed to translate consistently into improved clinical outcomes, with no differences in 28- or 60-day mortality or intensive care length of stay. Further study is needed to determine the role of resuscitative crystalloids other than Ringer lactate solution in burn injury.

[^]: Many burn centers do not use colloids based on these formulas in the 24- to 48-hour period.

DSW = dextrose 5% in water; FFP = fresh frozen plasma; LR = lactated Ringer; NS = normal saline; TBSA = total body surface area.

It is also important to remember that these formulas provide an estimate, and individual patient response should dictate ongoing resuscitative plans. Factors that can be associated with requirement of fluid volume above initially calculated amounts include concomitant injuries, electrical injury, inhalation injury, delays in resuscitation, dehydration before injury, alcohol or other substance abuse, and burn injury involving subcutaneous tissues (e.g., muscle). Over-resuscitation has become an increasing problem, and this phenomenon of excess...
fluid administration has been termed fluid creep.\textsuperscript{28} Potential contributors to fluid creep include inaccurate estimation of burn size, improper/inadequate titration of fluids, use of additional end points for resuscitation such as cardiac index or central venous oxygen saturation, increased sedation, and analgesic infusion use.\textsuperscript{28-31} The consequences of fluid creep include acute lung injury, intra-abdominal hypertension, abdominal compartment syndrome, and ischemic optic neuropathy.\textsuperscript{31-35} Potential mechanisms to reduce the risk of inadequate titration that have shown reductions in 24- and 48-hour resuscitative fluid volumes include nursing and computer-directed algorithms.\textsuperscript{36,37} The increased concern associated with fluid creep and the consequences of over-resuscitation have also led to renewed interest in the role of colloids in burn resuscitation.\textsuperscript{38}

Although many centers have returned to using colloids in burn resuscitation, use of colloids has existed since the initial resuscitative formulas. In fact, the original Parkland formula included an infusion of plasma after 24 hours.\textsuperscript{8,38} The theoretical benefits of colloid administration that have been shown in animal models for burn injury include increases in oncotic pressure and subsequent improvement in intravascular fluid retention, restriction of volume losses observed in burn injury, and fluid shifts from the vascular space to the lungs and interstitium. However, significant concerns regarding the ability of colloids to remain in the intravascular space in the initial 24 hours post-injury because of increased capillary permeability and data analyses suggesting increased mortality in burn injury with colloid administration contributed to a movement away from colloid administration starting in the 1960s.\textsuperscript{38} Not until the past decade with the documented consequences of the observed fluid creep has the potential role for colloids in burn resuscitation been reintroduced. Although most burn resuscitative formulas have historically used plasma for colloid resuscitation, several prospective studies have evaluated the role of albumin, as early as 1975.\textsuperscript{38} The initial small randomized controlled studies consistently found that albumin administration during burn resuscitation offers a significant fluid-sparing effect.\textsuperscript{39-42} However, most studies have failed to either evaluate or show clinical outcome benefit
associated with the use of albumin. More recently, Park and colleagues evaluated 159 patients 12 years and older with greater than 20% TBSA burn who were admitted to the burn intensive care unit before and after implementation of a burn resuscitation protocol that included early use of albumin. The resuscitation protocol allowed for conversion from lactated Ringer to albumin 5% continuous infusion at the same rate, if the 12-hour resuscitative fluid requirements would predict an excess of 6 mL/kg/% TBSA burn in the 24-hour resuscitative period. Although there was no difference in the total fluid volume required before and after implementing the albumin protocol, this study did show a significant clinical benefit to albumin use with a reduction in mortality (26 vs. 10%, p<0.01) and a decrease in duration of mechanical ventilation, vasopressor use, and incidence of abdominal compartment syndrome requiring surgical intervention. Although the role of colloids is unclear within burn resuscitation, they appear to play a role at least within patients requiring more than predicted resuscitative fluid volume.

Table 42.3 Examples of Current Formulas to Estimate Resuscitation Requirements for Pediatric Burn Patients
Pharmacologic Resuscitation with Ascorbic Acid

Reactive oxygen species have been identified as a key factor in endothelial dysfunction and subsequent hypoperfusion observed in sepsis and burn injury. Reactive oxygen species production occurs through several pathways, including enzymatic induction (e.g., endothelial nitric oxide synthase), uncoupling of mitochondrial respiration, and histamine activation of xanthine oxidase. Ascorbic acid, a known antioxidant, has been shown in vitro to reduce oxidative stress-mediated endothelial dysfunction and permeability, reduce impairment of microcirculatory flow, and improve macrophage activity. Animal models have replicated these in vitro findings and also found that ascorbic acid attenuates burn-related immunosuppression, lipid peroxidation, and vascular permeability. A single randomized controlled trial of 37 patients older than 16 years with severe burn

*Many burn centers do not use colloids according to these formulas in the 24- to 48-hour period.

LR = lactated Ringer; TBSA = total body surface area.
injury (greater than 30% TBSA burns) showed that patients who received high-dose ascorbic acid had significantly lower 24-hour resuscitative fluid requirements than did control patients (3.0 ± 1.7 vs. 5.5 ± 3.1 mL/kg/% TBSA burn, p<0.01). Both groups received resuscitation using the Parkland formula calculation, which was titrated to a urine output end point of 0.5–1 mL/kg/hour, with the intervention group receiving ascorbic acid diluted 10-fold with distilled water at 66 mg/kg/hour for 24 hours concurrently with Parkland formula resuscitation (see Table 42.2). The volume associated with ascorbic acid administration was accounted for in the 24-hour fluid intake determination. The difference in resuscitative volume requirements also translated to significant benefit with respect to improved $P_{aO_2}/fraction of inspired oxygen (Fio_2)$ ratios at 18, 24, 36, 48, and 72 hours after injury and a 9-day reduction in mechanical ventilation duration. Because of this small study, some burn centers implemented high-dose ascorbic acid resuscitation to counteract the observed fluid creep. Kahn and colleagues reported their experience with ascorbic acid (66 mg/kg/hour for 24 hours) in 17 patients compared with 16 control patients who received standard resuscitation without ascorbic acid. Patients who received high-dose ascorbic acid had a significant reduction in 24-hour resuscitative fluid requirements similar to what was observed by Tanaka and colleagues (3 vs. 5.5 mL/kg/% TBSA burn, p<0.05). Although these two small studies showed consistent benefits of high-dose ascorbic acid, concerns of osmotic diuresis and renal failure–associated calcium oxalate formation, based on animal data, were not adequately addressed in these clinical studies. Kahn and colleagues noted a higher urine output in patients receiving ascorbic acid (1.5 vs. 1 mL/kg/hour, p<0.05), which could support either osmotic diuresis or improved resuscitation and renal perfusion. However, the Kahn study failed to use standardized criteria for renal failure and did not evaluate the development of renal failure beyond the 24-hour period of ascorbic acid administration. Buehner and colleagues published a case series describing two patients treated with high-dose ascorbic acid for resuscitation of burn injury. Both patients developed acute kidney injury and, on autopsy, were found to have calcium
oxalate crystals within the renal tubules. To date, no studies have fully addressed the safety concerns with ascorbic acid resuscitation.

Another concern regarding high-dose ascorbic acid is the documented interference with point-of-care glucose measurements. Studies have documented significant increases in point-of-care glucose concentrations compared with serum laboratory glucose values of 10–200 mg/dL. In addition, the interference persists beyond the discontinuation of ascorbic acid infusion, ranging from a few hours to up to 24 hours after discontinuation. Caution should be taken when monitoring glucose values during vitamin C administration and for up to 24 hours after completion of therapy.

No studies have evaluated high-dose ascorbic acid–based resuscitation in pediatric patients with burn injury. However, a single randomized controlled study compared patients who received oral antioxidant supplementation (n=17) with vitamin C (1.5 times the upper intake level), vitamin E (1.35 times the upper intake level), and zinc (2 times the recommended dietary allowance) during days 2–8 after admission with patients who received no supplementation (n=15). For vitamin C, this dosing would translate to 600 mg for those 1–3 years of age, 975 mg for those 4–8 years of age, 1800 mg for those 9–13 years of age, and 2700 mg for those 14–18 years of age. Patients who received the antioxidant mixture including ascorbic acid had decreased lipid peroxidation (based on malondialdehyde concentrations) and improved wound healing. However, the clinical benefit of this intervention is limited because mortality was not evaluable on the basis of the strict inclusion criteria, and length of stay was not reported. According to the limited data showing outcomes benefits and the lack of safety data, high-dose ascorbic acid is not currently standard of care for the resuscitation of either pediatric or adult patients with burn injury.

**Inhalation Injury**

Up to 20% of patients hospitalized with burn injury present with inhalation injury. Inhalation injury describes a group of pulmonary injuries caused by the inhalation of chemical or thermal irritants that can
affect the upper or lower airways. Typically, these injuries can be further divided according to etiology: thermal injury to the upper airway above the glottis, injury throughout the pulmonary tree caused by chemical irritation, or toxicity systemically caused by carbon monoxide or cyanide inhalation. Thermal injury to the oropharynx results in pathophysiologic changes similar to those observed in cutaneous burn injury and can result in edema and ultimately airway obstruction during fluid resuscitation; therefore, the need for intubation for airway protection should be evaluated in patients at risk of inhalation injury (e.g., patients with stridor, severe facial burns, and burns greater than 50% TBSA). Injury to the lower airway is usually associated with irritation caused by by-products of incomplete combustion (e.g., sulfur dioxide, nitrogen dioxide, ammonia, chlorine, toxic aldehydes). Both epithelial and endothelial capillary cells of the airway are damaged, and significant increases in capillary permeability occur, resulting in accumulation of protein-rich fluid within the alveoli and impaired gas exchange. Additional mucociliary transport and clearance of bacteria is diminished, placing patients at higher risk of pneumonia.

Inhalation injury with concurrent cutaneous injury increases morbidity and mortality, fluid requirements for initial resuscitation, and risk of other pulmonary complications such as pneumonia. Although there have been significant advances in the management of cutaneous burn injuries in the past decades, there is limited information to guide both diagnosis and treatment of inhalation injury. Currently, there are no standard diagnostic criteria for inhalation injury, and clinicians rely primarily on a history of smoke exposure in a closed space, physical examination (e.g., soot in airway, singed nasal hairs, carbonaceous sputum), fiberoptic bronchoscopy, and carboxyhemoglobin concentrations. Management focuses on supportive care with mechanical ventilation, and the only pharmacologic interventions with evidence in humans at this time are nebulized heparin and acetylcysteine. Additional agents directed toward reducing bronchoconstriction and improving pulmonary blood flow, including nebulized β-agonists and nitric oxide, have shown potential benefits in animal models.
In addition to endothelial damage, airway obstruction occurs in inhalation injury because of the development of casts, fibrin deposition, and clot formation in the alveolar space. Nebulized heparin and acetylcysteine have been evaluated because of their potential role in reducing reactive oxygen stress and fibrin clot formation. Desai and colleagues first showed in a retrospective, observational study a significant benefit of nebulized heparin alternating with acetylcysteine with reduced requirements for reintubation and improved survival among 47 pediatric patients who received heparin 5,000 international units every 2 hours for 7 days after injury compared with 43 historical control patients. After this study, Holt and colleagues found no benefits with nebulized heparin 5,000 international units (5,000 international units/mL) with 3 mL of 20% acetylcysteine and albuterol (2.5 mg of 0.083% solution per 3 mL) in adult patients with inhalation injury in a retrospective review.

Miller and colleagues conducted a similar study in adult patients 18–80 years of age with smoke inhalation injury. In this observational pre/post-intervention study, 16 patients who received 10,000 international units of nebulized heparin mixed in 3 mL of 0.9% sodium chloride every 4 hours alternating with 3 mL of 20% acetylcysteine and 0.5 mL of albuterol for 7 days were compared with 14 historical controls. Significant improvement in lung injury score (LIS) for days 2–7, pulmonary compliance, and hypoxia scores, based on the \( \text{Pao}_2/\text{Fio}_2 \) ratios, were observed in patients receiving nebulized heparin/acetylcysteine and albuterol. Given these conflicting results, a small prospective, randomized, double-blind study compared two differing nebulized heparin strategies. Elsharnouby and colleagues compared 29 adult burn patients in the following two groups: a group receiving 5,000 international units of heparin in 3 mL of 0.9% sodium chloride nebulized alternating every 2 hours with 3 mL of 20% acetylcysteine and a group receiving 10,000 international units of heparin in 3 mL of 0.9% sodium chloride nebulized alternating every 2 hours with 3 mL of 20% acetylcysteine. This study found a significant improvement in LIS scores on days 5–7 after injury as well as a significant reduction in the duration of mechanical ventilation by 8 days.
in the group that received 10,000 international units heparin. According to analyses of these data, when using nebulized heparin with acetylcysteine in the adult patient with inhalation injury, a higher dosing (e.g., 10,000 international units) of heparin should be used. Limited data have been reported regarding the safety of nebulized heparin and acetylcysteine. Elsharnouby and colleagues were the first to report that neither dosing strategy (5,000 or 10,000 international units of nebulized heparin) affected platelet count or coagulation parameters (activated partial thromboplastin time and thrombin clotting time), and neither strategy was associated with the development of blood-tinged secretions. Because the quality of data supporting the use of nebulized heparin with acetylcysteine in both pediatric and adult patients with inhalation injury is low, there is considerable variation in practice among burn centers with respect to nebulized heparin/acetylcysteine. A prospective, randomized, placebo-controlled, double-blind study is currently recruiting 116 patients to receive nebulization of either 25,000 international units of heparin (5 mL) or placebo (0.9% sodium chloride 5 mL) without acetylcysteine every 4 hours for up to 14 days after injury to try to provide further evidence defining the role of nebulized heparin in the management of inhalation injury.61

**Carbon Monoxide and Cyanide Toxicity**

Many fatalities at the scene occur because of carbon monoxide toxicity. Carbon monoxide is a colorless, odorless, non-irritating gas produced by incomplete combustion of carbon-containing compounds. Carbon monoxide competes with oxygen for hemoglobin binding, but it displaces oxygen and lowers oxygen delivery because of a 200- to 250-fold higher affinity for hemoglobin than for oxygen. Because of the similar absorbent spectrums of oxyhemoglobin and carboxyhemoglobin, pulse oximetry cannot distinguish between the two. The Pao\textsubscript{2} measurements are also limited in carbon monoxide exposure and may not reflect the degree of toxicity. Complications associated with carbon monoxide toxicity generally involve neurologic symptoms, with severity based on the measured carboxyhemoglobin concentration ranging from confusion and headaches to coma (Table 42.4). Use of neurologic
symptoms can be limited in patients with burn injury because many have received sedating medication before presentation to the emergency department. Definitive diagnosis of carbon monoxide toxicity relies primarily on laboratory confirmation of carboxyhemoglobin concentration. Carboxyhemoglobin concentrations greater than 3% in nonsmokers and greater than 10% in smokers indicate exposure to carbon monoxide.\textsuperscript{55}

Current guidelines for the management of carbon monoxide toxicity recommend administration of 100% Fio\textsubscript{2} for patients with carboxyhemoglobin concentrations greater than 10%. Administration of 100% Fio\textsubscript{2} reduces the half-life of carboxyhemoglobin from 250 minutes at room air to 40–60 minutes. Although this can be administered by facemask in patients who are alert, patients with altered mental status should be intubated and mechanically ventilated with 100% Fio\textsubscript{2} until carboxyhemoglobin concentrations fall below 5%. Hyperbaric oxygen (HBO) can further reduce the half-life of carboxyhemoglobin, but the ABA does not currently support the use of HBO as standard of care in carbon monoxide toxicity. The hyperbaric chamber can introduce challenges into the acute phase of burn injury.
care because it may limit nursing and physician access to the patient during a time when frequent assessments are necessary. The impact of HBO on long-term neurologic complications of carbon monoxide is controversial, but a Cochrane review of six studies found no benefit with HBO. Currently, HBO should only be considered in patients whose carboxyhemoglobin concentrations remain elevated despite aggressive oxygen therapy.

Cyanide is also produced by the combustion of typical household materials, and concurrent carbon monoxide and cyanide exposure is common in house fires. Cyanide is normally found in concentrations of 0.3–0.5 mg/L, and enzymes convert the potentially toxic cyanide to thiocyanate at a rate of 0.017 mg/kg/minute. However, in acute cyanide exposure, these enzymes are saturated, and cyanide accumulates. Cyanide inhibits cellular respiratory by interfering with the cytochrome oxidase system, ultimately resulting in hypoxia and a metabolic lactic acidosis. Symptoms of cyanide toxicity closely resemble those of carbon monoxide toxicity and range from dizziness and headache to coma, seizures, and shock. It is difficult to diagnose cyanide toxicity in the burn population solely on presentation, but unfortunately, measurement of cyanide concentrations is not available at most medical centers. Therefore, clinicians should consider empiric treatment for cyanide toxicity when at least two of the following are present: (1) neurologic symptoms including altered mental status, coma, or convulsions; (2) visible soot in mouth, nares, or sputum; or (3) metabolic acidosis with an elevated lactate concentration greater than 8 mmol/L.

Treatment options for cyanide toxicity (amyl nitrite perles, 10% sodium nitrite, 25% sodium thiosulfate, and hydroxocobalamin) aim to increase the metabolism and elimination of cyanide (Table 42.5). Both amyl nitrite and sodium nitrite increase cyanide elimination by first inducing methemoglobinemia. Cyanide then binds preferentially to methemoglobin, forming cyanomethemoglobin, which then essentially sequesters the cyanide. As cyanide dissociates from methemoglobin, it can be metabolized through normal pathways to non-toxic thiocyanate. Although the nitrites (amyl nitrite and sodium nitrite) allow
for elimination of cyanide, the induced methemoglobinemia reduces the oxygen-carrying capacity of hemoglobin, furthering the hypoxic state of patients with inhalation injury, especially in light of carbon monoxide toxicity. Therefore, both amyl nitrite and sodium nitrite are contraindicated in patients presenting with smoke inhalation. Sodium thiosulfate also allows for the metabolism of cyanide to thiocyanate with minimal adverse effects by acting as a sulfhydryl donor. Hydroxocobalamin also has minimal complications and does not interfere with oxygen delivery. Hydroxocobalamin chelates cyanide, forming cyanocobalamin, which is eliminated renally. Limited data for these agents exist, and no randomized controlled comparative studies support the use of one agent over another. The nitrites are generally avoided because of their adverse effect profile, and in cutaneous burn injury, hydroxocobalamin can make an ongoing assessment of burn wounds challenging because of significant skin and mucus membrane discoloration. Hydroxocobalamin is also known to interfere with colorimetric laboratory assays used for liver enzymes, serum creatinine, electrolytes, met-hemoglobin, and carboxyhemoglobin for several days after administration, further limiting its use in burn injury.

With efficacy data lacking, the decision of which agent to use is based on adverse effect profile. Therefore, sodium thiosulfate monotherapy is considered standard of care, specifically in patients with cutaneous burn injury.

NUTRITION SUPPORT AND METABOLIC MODULATION

Burn injury elevates the normal metabolic rate, resulting in the loss of lean body mass and muscle wasting if there is no intervention. In both adult and pediatric patients, estimating caloric requirements with indirect calorimetry, using serial REE measurements, tends to be more accurate than using predictive equations. Enteral nutrition should be initiated within the ebb phase because the hypermetabolic state associated with the flow phase can lead to a doubling of the normal REE. Patients should not be fed enterally if they are experiencing
hypovolemic shock, showing signs of instability and hypoperfusion, or experiencing visible abdominal distension. Early enteral feeding has been shown to decrease hospital length of stay and facilitate maintenance of admission weight.\textsuperscript{69} Because burn patients oxidize amino acids much more quickly than healthy individuals, the recommended amount of protein is 1.5–2.0 g/kg/day if renal and liver function is normal.\textsuperscript{70} When studied in pediatric patients with severe burns (greater than 40\% TBSA), enteral nutrition that was supplied predominantly as carbohydrates rather than fat improved the balance of skeletal muscle protein.\textsuperscript{68}

Nonpharmacologic measures to reduce REE include maintaining room temperature at 30°C–32°C, providing early excision and grafting of wounds, and promptly treating infections, as well as providing proper sedation and pain control.\textsuperscript{11} There are a variety of pharmacologic interventions to help attenuate the hypermetabolic response in burn injury and decrease catabolism, enhance lean mass accretion, and maintain protein stores. These agents include oxandrolone, recombinant human growth hormone (rhGH), and adrenergic blockers.

Oxandrolone, an anabolic androgenic steroid, promotes protein synthesis and skeletal muscle growth and decreases time for wound healing. Oxandrolone should be dosed at 10 mg twice daily in adult patients, and the dose should be reduced in older adult patients to 5 mg twice daily because of the increased risk of adverse effects. Studies have shown oxandrolone to decrease hospital length of stay and patients to regain weight and lean mass faster than placebo when initiated 5–7 days after admission.\textsuperscript{71,72} Doses of 0.1 mg/kg twice daily in pediatric patients have also been shown to improve lean body mass, serum visceral proteins, and muscle strength while promoting weight gain and increasing mineral bone content.\textsuperscript{11} Even when treated for up to 1 year post-burn, oxandrolone improved lean body mass at 6, 9, and 12 months after the burn, and bone mineral content was also improved.\textsuperscript{73} Pediatric patients who received oxandrolone for 1 year post-burn also show improvements for up to 5 years after treatment in height, bone mineral content, cardiac work, and muscle strength, with the greatest improvements seen in children ages 7–18 years.\textsuperscript{74}
Adverse effects of oxandrolone include increased hepatic transaminases, and these should be monitored weekly while on oxandrolone therapy. If significant or persistent elevations of serum liver function tests occur, oxandrolone should be discontinued. Patients should not receive oxandrolone if they are pregnant or have a history of liver disease or cancer. Alterations in cholesterol have also been noted with oxandrolone, including lowering of high-density lipoprotein cholesterol and elevations in total or low-density lipoprotein cholesterol.\textsuperscript{75} Oxandrolone has also been associated with the formation of edema and exacerbating heart failure.\textsuperscript{11,75} Compared with rhGH in adult patients, oxandrolone at 10 mg twice daily had significantly fewer hyperglycemia complications, and similar wound healing benefits were seen between the two agents.\textsuperscript{76} The optimal duration of oxandrolone therapy has not been clearly defined, and the safety of using oxandrolone in pediatric patients younger than 1 year has not been established.

IV = intravenous(ly).
Recombinant human growth hormone has also been used to promote anabolism in burn injury. Studies looking at administering rhGH in patients with large burns (greater than 40% TBSA) have suggested that rhGH promotes wound healing of the burn wound and donor sites in both adults and children, as well as decreases length of hospital stay. Complications of using rhGH include increased rates of hyperglycemia, which can be up to 2.65 times more likely in adults and children who receive rhGH than in placebo. Other safety concerns with rhGH include an increase in morbidity and mortality seen in critically ill patients without burn injury, mostly attributed to organ failure, septic shock, or infection that could not be controlled.

Treatment with β-blockers in patients with severe burns reduces heart rate, which decreases supraphysiologic thermogenesis and REE. When pediatric patients with severe burns are treated with propranolol, there is an attenuation of the hypermetabolic response and a reversal of the muscle-protein catabolism. Propranolol doses for children are initiated at 0.33 mg/kg every 4 hours and are titrated to achieve a 20% decrease in heart rate compared with the 24-hour heart rate immediately before treatment. When used for up to 12 months post-burn, propranolol treatment in pediatric patients reduced REE, decreased accumulation of central mass and central fat, prevented bone loss, and improved lean body mass accretion. Propranolol treatment in pediatric patients is relatively safe, with hypotension being the most common adverse effect.

Data to support β-blockade in adult burn patients are more limited. A retrospective cohort study compared adult burn patients who were previously on β-blockers, those who were initiated on β-blockers in the hospital, and a control group. Those who were on β-blockers before admission had a significant reduction in healing time, and these patients tended to spend less time in the hospital. However, patients previously not on β-blockers who were initiated after their burn injury tended to have increased hospital and intensive care unit length of stay, as well as a higher mortality, although 60% of these patients were initiated on β-blockers for an in-hospital cardiac complication, such as ischemia or atrial fibrillation. Prospective, randomized, clinical studies are needed
to truly determine the outcomes of using β-blockers in adult burn patients.

---

### CHALLENGES IN THE MANAGEMENT OF SEPSIS AND SEPTIC SHOCK IN BURN INJURY

**Recognition of Sepsis and Infection in Burn Injury**

**Box 42.2. ABA Consensus Definitions for the Sepsis Continuum in Patients with Burn Injury**

**Sepsis**
Documented infection PLUS at least three of the following:

- Temperature $> 39^\circ C$ or $< 36.5^\circ C$
- Progressive tachycardia
  - Adults $> 110$ beats/min
  - Children $> 2$ standard deviations (SD) above agespecific norms
- Progressive tachypnea
  - Adults $> 25$ beats/min not ventilated, or minute ventilation $> 12$ L/min ventilated
  - Children $> 2$ SD above agespecific norms
- Thrombocytopenia (only applicable at least 3 days after initial resuscitation)
  - Adults $< 100,000$/microliters
  - Children $< 2$ SD below agespecific norms
  - Hyperglycemia in the absence of preexisting diagnosis of diabetes mellitus
    - Plasma glucose $> 200$ mg/dL before treatment
Insulin resistance (e.g., 25% increase in insulin requirements over 24 hr)

- Inability to continue enteral feeding for at least 24 hr
  - Abdominal distension
  - Enteral feeding intolerance
  - Uncontrollable diarrhea (> 2.5 L/day for adults or > 400 mL/day for children)

**Severe Sepsis**
- This term is not recognized by the ABA

**Septic Shock**
- Sepsis PLUS traditional hemodynamic alterations

Because of the massive inflammatory response associated with severe burn injury, the traditional criteria for recognizing sepsis (e.g., leukocytosis, fever, tachypnea, and tachycardia) cannot be used. Traditional definitions for systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock are discussed in chapter 15, “Severe Sepsis and Septic Shock.” In patients with burn injury, the ABA defines sepsis as a trigger for concern for infection that must include at least three of six possible criteria, together with documented infection (Box 42.2). The ABA does not recognize the term severe sepsis, and the criteria for septic shock include those defining sepsis plus the traditional hemodynamic parameters defined by the Surviving Sepsis Campaign. Of note, these burn-specific criteria were initially developed as an initiative of a consensus conference, and they have not yet been fully validated. Subsequently, studies have confirmed that the traditional SIRS criteria have poor predictive value for sepsis within the burn population. Almost all patients with severe burn injury have traditional SIRS criteria, regardless of the suggestion of sepsis, and more than 95% of patients met SIRS criteria, even
during periods of clinical stability. Although the ABA criteria have improved clinical value, additional criteria to assist in more accurately identifying sepsis in this population have been proposed. Additional factors to consider include a more stringent heart rate threshold (heart rate greater than 130 beats/minute), serum glucose concentrations greater than 150/dL or increasing glycemic variability, hemodynamic instability (mean arterial pressure less than 60 mm Hg or use of vasoactive agents), and evidence of pulmonary and additional diagnostic laboratory values (procalcitonin and serum N-terminal pro-B-type natriuretic peptide).82-84

**Pharmacokinetic and Pharmacodynamic Considerations for Antimicrobial Agents in Burn Injury**

The hypermetabolic alterations observed in severe burn injury are accompanied by significant pharmacokinetic alterations that can affect optimal drug dosing in this complex population.85,86 Although there is published literature to aid practitioners in determining dosing adjustments for this population, there are limitations to the data, including significant variability in methodology and patient characteristics and small sample sizes. These studies have also shown that burn severity alone cannot predict the dosing alterations required to overcome the pharmacokinetic alterations. Practitioners should consider standard key criteria when optimizing drug dosing in burn patients (Box 42.3).

During the initial ebb phase, patients with severe burn injury have an initial decrease in creatinine clearance that returns to normal or above normal after fluid resuscitation is achieved.87,88 Significant alterations in hepatic metabolism occur as well during the flow phase because of increased hepatic perfusion. Phase 1 metabolism (i.e., oxidation) is significantly decreased, and phase 2 metabolism (i.e., conjugation, glucuronidation) is either unchanged or increased. Significant increases in volume of distribution also occur as a result of fluid resuscitation, hyperdynamic circulation, and capillary leak. These alterations have an impact on pharmacokinetics, primarily for drugs that distribute into the extracellular fluid (e.g., aminoglycosides). Decreased protein synthesis,
including both albumin and total protein concentrations, results in increased free concentrations of highly protein bound medications (e.g., phenytoin, valproic acid). In contrast, increases in acute phase proteins, including $\alpha_1$-acid glycoprotein, can significantly lower free concentrations of drugs that bind to $\alpha_1$-acid glycoprotein after burn injury (e.g., imipramine and lidocaine). Antimicrobial agents with specific dosing recommendations to overcome these pharmacokinetic changes are summarized in Table 42.6.

OTHER SUPPORTIVE THERAPY IN BURN INJURY

Glycemic Control in Burn Injury

**Box 42.3. Key Considerations for Pharmacokinetics in Burn Injury**

1. Burn size and depth
   - Burns of increasing severity are more likely associated with a profound hypermetabolic response
2. Age
   - Older patients are more likely to have preexisting renal and hepatic insufficiency
3. Time since burn injury
   - Depending on timing, pharmacokinetic alterations differ (i.e., ebb vs. flow phase)
   Although metabolic rate can remain increased for years, early in the flow phase, the alterations are more profound
4. Creatinine clearance
   - Although calculated creatinine clearance may not be accurate in this population, it can be used to trend changes in renal function across time
5. Serum protein concentrations
   - Decreased albumin concentrations and increased $\alpha_1$-acid glycoprotein may affect free drug concentrations

6. Volume status
   - Once adequately fluid resuscitated, volume of distribution will likely be increased because of added fluid volume and capillary leak.

7. Presence of sepsis as defined by the ABA
   - Sepsis is known to increase hypermetabolism.

8. Drug properties
   - Specifics regarding volume of distribution, protein binding, metabolism, and modes of elimination are needed to estimate response in patients with burn injury.

9. Other information
   - Data from indirect calorimetry and interventions known to decrease metabolic rate (i.e. excision and grafting) can be used to augment assessment of hypermetabolism.

Table 42.6  Suggested Antimicrobial Dose Adjustments in Patients with Burn Injury\textsuperscript{86,87,89-102}
During the flow phase of burn injury, hyperglycemia and insulin resistance are common. Both early and prolonged hyperglycemia after burn injury is associated with poor clinical outcomes in the burn
population. Hyperglycemia has been shown to delay wound healing, promote lean muscle losses, and suppress immune function.\textsuperscript{103,104} Although a significant body of research supports the benefits of glucose control within the critically ill population, limited data are available within the burn population. Van den Berghe’s pivotal study supporting intensive insulin control in the surgical intensive care unit included only 8 total burn and trauma patients from the total 1,548 randomized subjects.\textsuperscript{105} Most burn centers aim for euglycemia for patients with burn injury, based on extrapolation of the NICE-SUGAR (Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation) study and the assumption that avoiding hyperglycemia may improve wound healing, reduce infections, and possibly reduce mortality.\textsuperscript{13,103,106,107} Insulin itself has been extensively studied in burn injury as an anabolic agent and has shown anti-inflammatory properties. It reduces muscle catabolism and improves protein synthesis and wound healing.\textsuperscript{108-110} In 2005, Pham and colleagues reported their experience with tight glycemic control (glucose target 90–120 mg/dL) by insulin infusion in 33 pediatric burn patients with a TBSA greater than 30% injured compared with 31 historical control patients.\textsuperscript{107} Patients who received the intensive insulin protocol had a lower reported incidence of urinary tract infections and a higher rate of survival, despite similar baseline characteristics. In an adjusted logistic regression analysis, intensive insulin was associated with an adjusted odds ratio of 5.52 in favor of survival, although this failed to reach statistical significance (p=0.06). Although prevalence of hypoglycemia was not reported, administration of dextrose 50% for glucose less than 50 mg/dL was required on nine occasions in the tight glycemic control group, with no occurrences in the control group. Given these results, a prospective, randomized trial of pediatric patients with a TBSA greater than 30% burned compared tight glycemic control (n=49, glucose target 80–110 mg/dL) with conventional control (n=137, glucose target 140–180 mg/dL).\textsuperscript{108} Intensive insulin was associated with significant reductions in the rate of infection and sepsis compared with conventional control. Although there were no differences between the groups in REE, intensive insulin significantly modulated the acute
inflammatory response and resulted in improvement in lean muscle mass and bone density compared with control. The intensive insulin group also had a lower mortality rate than did controls, although this failed to reach statistical significance (4 vs. 11%, p=0.14). As observed in other critically ill populations, hypoglycemia is associated with increased morbidity and mortality with burn injury, and intensive insulin is associated with increased incidence of hypoglycemia.\textsuperscript{111}

There are no randomized, prospective studies regarding glycemic control in adult patients with burn injury. A retrospective observational study showed significantly decreased rates of pneumonia and urinary tract infections with an insulin protocol targeting a blood glucose of 100–140 mg/dL in 152 adult burn injured patients with percent TBSA injured of 19\% in the control group and 15\% in the insulin protocol group.\textsuperscript{106} This protocol was also deemed safe because no differences in the rate of hypoglycemia were observed. In another retrospective observational study of 46 patients with severe burns, early glycemic control also improved outcomes.\textsuperscript{112} A standardized protocol was used for all patients, targeting a glucose of 110–150 mg/dL with sliding-scale insulin administration and insulin infusion initiation with repeated glucose concentrations greater than 200 mg/dL. Failure to achieve early glycemic control, defined as achievement of a daily average blood glucose of 150 mg/dL or less for a minimum of 2 consecutive days by post-burn day 3 was independently associated with an increase in mortality by 6.75-fold. Although data are limited in both pediatric and adult patients with burn injury, it is generally accepted that protocols to maintain euglycemia while avoiding both hyperglycemia and hypoglycemia (e.g., target glucose range 90–140 mg/dL) should be implemented as standard of care in this population.\textsuperscript{111}

**Venous Thromboembolism Prophylaxis**

Clinical diagnosis of deep venous thrombosis in patients with burn injury can be challenging. Clinical signs that are common to both burn injury and deep venous thromboembolism include erythema, edema, and tenderness. Current data suggest a much lower incidence of venous thromboembolism (VTE) in patients with burn injury than in the general
trauma population. Reported prevalence in burn patients is 1%–6%, whereas in trauma patients, reported prevalence is 5%–63%, depending on methods of diagnosis and means of mechanical or pharmacologic prophylaxis.\textsuperscript{113-117} The current CHEST guidelines recommend pharmacologic prophylaxis with either low-dose unfractionated heparin or low-molecular-weight heparin agents with or without mechanical prophylaxis for trauma patients.\textsuperscript{118} Literature is limited to establish the efficacy of varying VTE prophylaxis therapies in patients with burn injury, which forces extrapolation from data published in non-burn injury populations. Routine VTE prophylaxis with either unfractionated heparin or low-molecular-weight heparin is recommended by the ABA for patients with additional risk factors for VTE and no contraindications to treatment. Known VTE risk factors in burn injury include advanced age, male sex, alcoholism or tobacco use, morbid obesity, extensive or lower-extremity burns, concomitant lower-extremity trauma, use of a femoral or other central venous catheter, increased number of surgeries or blood transfusions, and prolonged immobility.\textsuperscript{113,119} If contraindications to pharmacologic prophylaxis exist because of bleeding risk, patients should receive mechanical prophylaxis at least until this risk resolves. However, mechanical prophylaxis can prove to be potentially difficult in patients with leg burns, depending on location of injury. The ABA guidelines do not recommend one agent over another for pharmacologic prophylaxis, but a retrospective review showed no difference in the efficacy of unfractionated heparin versus enoxaparin.\textsuperscript{120} This 10-year retrospective, cohort analysis compared patients who received prophylaxis with low-dose unfractionated heparin (n=600) or enoxaparin (n=511) with a primary end point of acute VTE according to ICD-9 coding. Among the enoxaparin-treated patients, 109 received 30 mg twice daily, and 402 received 40 mg once daily, whereas the patients given low-dose unfractionated heparin received 5,000 units twice daily. Five patients who received low-dose unfractionated heparin developed VTE (three with deep venous thromboembolism and two with pulmonary embolism), whereas no patients in the enoxaparin group developed VTE. Limitations of this study include twice-daily
heparin dosing, significant baseline differences between groups including a higher number of VTE risk factors in the low-dose unfractionated heparin group, and retrospective study design. This is the only comparative study for low-dose unfractionated heparin and low-molecular-weight heparin in burn injury, and the ideal prophylactic agents therefore remain uncertain at this time.

Recent concerns regarding low-molecular-weight heparin dosing in the critically ill population have indicated a possible role for dose titration using anti-factor Xa (anti-Xa) concentration. Lin and colleagues evaluated 74 patients with burn injury who received enoxaparin 30 mg every 12 hours, which was then titrated by 20% increments to achieve a goal anti-Xa concentration of 0.2–0.4 units/mL. Initial dose of 30 mg every 12 hours resulted in concentrations less than the targeted goal in 76% of the patients. On titration, the median dose to achieve an anti-Xa concentration within the goal range was 33% of the normal dosing at 40 mg every 12 hours. However, anti-Xa concentrations have not been correlated with clinical outcomes, and two patients with appropriate anti-Xa concentrations developed VTE in this study.

The calculation identified from this study for twice-daily enoxaparin dosing \[\text{dose (mg)} = 22.8 + (3.3 \times \% \text{TBSA/10}) + (1.89 \times (\text{weight in kg})/10] was validated in a comparison of protocolized enoxaparin calculation and titration with historical controls by Faraklas and colleagues. This comparison study found that use of this prophylactic enoxaparin dose calculator was associated with a significantly higher proportion of patients with an anti-Xa concentration within goal range (0.2–0.4 unit/mL) with the initial measurement and fewer patients who failed to achieve goal range before discontinuing enoxaparin therapy. However, two patients—one in the calculation group and one in the control group—developed VTE despite adequate anti-Xa concentrations. Although anti-Xa concentrations are used in some institutions for enoxaparin monitoring, additional research is needed to determine the role of anti-Xa concentrations and enoxaparin titration in the burn population, and data correlating anti-Xa concentrations and clinical outcomes are lacking.
MANAGEMENT OF SPECIAL POPULATIONS

Electrical Injury
Electrical injury accounts for 3.7% of all patients presenting with burn injuries, with higher rates among adults up to age 60 years than among children and older adults.\textsuperscript{1} Electrical injuries are responsible for greater than 500 deaths annually in the United States.\textsuperscript{1,2,3} The primary cause of death is cardiac or respiratory arrest.\textsuperscript{1,2,4} Most electrical injuries occur in adults and are work related (61.1%). Although electrical injuries are rarer in children, they often occur within the home, and patients present with oropharyngeal injuries from biting on live wires.\textsuperscript{1,2,4}

Injuries caused by electrical exposure are unique because they involve direct damage from the electricity as well as indirect injuries.\textsuperscript{1,2,3} Direct damage results from the effect of the electrical current directly on tissues involving electrical charge (e.g., cardiac complications), as well as conversion of the energy to heat and the subsequent tissue necrosis. Indirect injuries can be caused by muscular contractions triggered by the electrical impulses or other associated trauma, depending on the circumstances surrounding the electrical exposure (e.g., spinal cord injury or traumatic brain injury secondary to fall). The extent of the electrical injury is determined by the electrical voltage and resistance within the tissues exposed (i.e., lowest amount of resistance in nerves, blood, muscles; highest amount of resistance in bones, tendons, fat). Higher voltage (greater than 1000 V) is associated with more severe injury than is lower voltage.

Electrical injury can cause multisystem dysfunction and is associated with higher complication rates than other burn injuries, including development of cardiovascular, neurovascular, cutaneous, and pulmonary complications.\textsuperscript{1,2,3} Electrical exposure can result in the direct necrosis of myocardium as well as arrhythmias. The severity of the damage is proportional to voltage and is more severe with AC (alternating current) than with DC (direct current). Cardiac dysrhythmias can occur even with low voltage, but high-voltage current exposure carries a higher risk of ventricular asystole. Patients with electrical injury should initially be assessed with an electrocardiogram
(ECG). Patients with a normal initial ECG are considered at low risk of late arrhythmias, whereas patients with transthoracic current, tetany, loss of consciousness, or a high-voltage source (greater than 1000 V) may need continuous telemetry. Echocardiogram and monitoring of cardiac enzymes may also be warranted. Severity of cutaneous electrical burn injury is related to voltage and duration of exposure. Because of alterations in resistance as the result of moisture, minimal cutaneous damage may be visible on examination, whereas the subcutaneous tissue may have extensive necrosis. Therefore, the use of percent TBSA injured to determine resuscitative needs may grossly underestimate fluid volume requirements for patients with electrical injury. Higher-than-expected volumes may be required to maintain a goal urine output of 0.5–1 mL/kg/hour.

Patients presenting with electrical injury may have seizures, neurologic deficits, and tetanic muscle contractions. Common presenting symptoms include confusion, loss of consciousness, and difficulty with recall. In addition, tetany can result in rhabdomyolysis and subsequent renal failure. Monitoring of creatinine kinase and urine myoglobin and ensuring adequate fluid resuscitation are necessary to prevent renal insufficiency in this population.

Frostbite
Frostbite is a clinical diagnosis, and it is typically defined as the acute freezing of tissues when exposed to temperatures below the freezing point of intact skin. Historically, military personnel were considered at the greatest risk of developing frostbite. More recently, risk factors that are commonly identified include homeless people, alcohol or illicit drug consumption, and psychiatric illness.

Classification of frostbite injury is applied once the tissues have been rewarmed, and it is categorized into four degrees. First-degree frostbite injuries present with a numb central white plaque with surrounding edema. In second-degree injury, blisters form with surrounding edema and erythema. Third-degree injury is characterized by hemorrhagic blisters that result in a hard black eschar about 2 weeks later. Fourth-degree injury produces a complete necrosis and
Initially, patients may present with symptoms of numbness in the affected areas. Once the tissues are re-warmed, the numbness will fade, and a throbbing sensation may begin that can last for days or weeks. Pain is managed with opioids or nonsteroidal anti-inflammatory drugs (e.g., ibuprofen).

Treatment of frostbite injury begins with rewarming of the affected tissues, typically with warm water at 40°C–42°C. The temperature of the water should be carefully monitored not to reach a threshold that could potentially inflict a scald burn injury given that the patient may be unable to sense the temperature. Once the tissues have been rewarmed, the second goal of treatment is to restore arterial flow. One way to achieve this is using tissue plasminogen activator (tPA). Studies have suggested that treatment with tPA can decrease the number of amputations in patients with frostbite affecting the extremities. Patients with frostbite injury are typically considered for tPA therapy if they present within 24 hours of injury, have evidence of vascular compromise on physical examination, and have significant injury consisting of second-degree frostbite. Patients are often excluded from tPA therapy if any of the following apply: recent surgery or major trauma, uncontrolled psychiatric illness or active withdrawal from an illicit substance or alcohol, pregnancy, recent cerebral vascular accident or brain metastasis, recent gastrointestinal bleed, severe hypertension, bleeding diathesis, or irreversible ischemia (presenting greater than 24 hours from injury). Treatment of frostbite in pediatric patients with tPA has not been evaluated. Both intra-arterial and intravenous administration of tPA has been investigated. Early surgical intervention is typically not indicated in frostbite injury. The adage “Frostbite in January, amputation in July” is often used to describe frostbite injury. Rarely, escharotomy or fasciotomy may be indicated if compartment syndrome develops. However, if any surgical intervention is warranted in severe injury, it is often delayed for weeks to months post-injury.

As with any burn injury, prevention is the best way to avoid frostbite injury. Individuals should use protection from the environment with
multilayer clothing that is dry and non-compressing. Awareness of warning signs such as cold, pain, and numbness should prompt individuals to seek shelter and warmth.

**Chemical Burns**

Chemical burns account for about 3% of admissions to burn centers every year, with almost 50% of these injuries occurring in a work-related setting, although many injuries can occur with exposure to common household chemical products.\(^1\) Acidic agents can cause a caustic injury and typically account for less than half of chemical burn injuries.\(^{128}\) Alkali substances, by contrast, can cause liquefaction destruction and tend to penetrate deeper, creating a worse burn injury. Alkali injuries tend to make up more than half of injuries caused by chemicals.\(^{128}\)

Initial treatment of any chemical burn is immediate removal of the substance to prevent further tissue damage, such as removal of affected clothing and continuous irrigation with water or saline until skin pH returns to normal using litmus paper. Injuries to the eyes should be irrigated copiously and should be evaluated by an ophthalmologist. Some chemicals have specific treatment to prevent further tissue damage, such as burns caused by hydrofluoric acid. Free fluoride ions immobilize intracellular calcium and magnesium, causing extreme pain to the affected areas. Treatment with topical calcium gluconate gel to the burned areas is the mainstay of therapy to reduce the pain. Intravenous calcium gluconate, magnesium sulfate, or both may be indicated.

**CONCLUSION**

Patients with burn injury constitute a unique subset of the critically ill population. Pharmacists can play a key role with respect to optimizing care, from managing inhalation injury and metabolic modulation to recognizing sepsis and optimizing medication dosing on the basis of pharmacokinetic/pharmacodynamic alterations. The ABA recognizes the importance of the pharmacist in the care of this population and
requires the involvement of a pharmacist with an understanding of the pharmacokinetic implications for patients with acute burn injuries for a burn center to become ABA verified.

LEARNING OBJECTIVES

1. List the components of the primary survey.

2. Explain the rationale for each component of the primary survey (ABCDE).

3. List the classes of hemorrhagic shock.

4. Describe the components and their roles in the massive transfusion protocol.

5. Evaluate the data for support of tranexamic acid in the management of traumatic hemorrhage.

6. Compare the data for anticoagulant versus antiplatelet therapy in the management of blunt cerebrovascular injury.

7. Evaluate the data for neuroprotection in traumatic brain injury (TBI) management.

8. Compare mannitol with hypertonic saline in the management of intracranial hypertension.

9. Review the data supporting the management of early seizures.
10. State the complications of spinal cord injury (SCI).
11. Review the evidence for steroids in SCI.
13. Review the evidence for somatostatin/octreotide in the management of enterocutaneous fistulas.
14. Review the pharmacologic treatment options for the management of short bowel syndrome.
15. Recall the evidence for the prevention of contrast-induced nephropathy.
17. State the pharmacokinetic challenges with low-molecular-weight heparin dosing in trauma.

ABBREVIATIONS IN THIS CHAPTER

IH  Intracranial hypertension
INTRODUCTION

Traumatic injury is a significant health care concern, accounting for almost 200,000 deaths in the United States in 2010, and is the No. 1 cause of death among people 1–44 years of age and the No. 3 killer overall.¹ This translates to an economic burden of around $406 billion annually related to health care costs and loss of productivity.² Although treatment of patients with traumatic injury is primarily surgical in nature, the clinical pharmacist plays a critical role in optimizing drug therapy because drug therapy is an essential part of the support care in these patients. This chapter will review the initial evaluation of the trauma patient, the physiologic changes related to traumatic injury, and the various types of traumatic injuries and the subsequent complications that require pharmacologic intervention.
INITIAL EVALUATION OF THE PATIENT (ADVANCED TRAUMA LIFE SUPPORT)

Initial evaluation of the trauma patient involves a systemic approach, divided into a primary and secondary survey, to stabilize the patient and identify any life-threatening conditions.

Primary Survey

The primary survey encompasses a series of steps designed to identify life-threatening injuries and immediately initiate management. It involves Airway maintenance with cervical spine protection, Breathing and ventilation, Circulation with hemorrhage control, Disability with respect to neurological status, and Exposure/environment (ABCDE).³

Airway Maintenance

Airway maintenance is of utmost importance for the trauma patient. Pulse oximetry is used as an adjunct to the primary survey to detect and monitor hypoxia. During airway maintenance, the patient’s ability to maintain and protect the airway is assessed while maintaining cervical spine precautions. Some indications for securing a definitive airway when patients are unable to protect their own airway include unconsciousness or an obtunded neurological state (defined as a Glasgow Coma Scale [GCS] score less than 8), severe maxillofacial fractures, risk of aspiration (e.g., vomiting or bleeding), and risk of obstruction (e.g., stridor, laryngeal or tracheal injuries, neck hematoma). Concern for ventilation or oxygenation and the need for a definitive airway may arise in patients presenting with apnea; inadequate respiratory efforts such as tachypnea, hypoxia, hypercarbia, and cyanosis; severe closed head injury (with need for brief hyperventilation if acute neurological decompensation occurs); or massive blood loss and need for large-volume resuscitation. A definitive airway is defined as a cuffed endotracheal tube in the trachea, which is often achieved by rapid sequence intubation (RSI).⁴ When RSI fails to secure the airway, a surgical airway becomes necessary.
Breathing and Ventilation

After airway assessment, the trauma patient is evaluated for breathing and ventilation, which includes adequate oxygenation and carbon dioxide exchange. A patent airway does not automatically ensure adequate ventilation.\(^5\) Pulse oximetry allows noninvasive measurement of oxygenation; however, it can be inaccurate in different settings such as vasoconstriction, carbon monoxide poisoning, hypothermia, or severe anemia.\(^5\) Therefore, an arterial blood gas is often required to assess the partial pressure of oxygen. Evaluation of breathing by inspecting chest wall movement, auscultation of breath sounds, and percussion is essential to help detect any abnormalities that need immediate attention such as a pneumo- or hemothorax. A tension pneumothorax can develop from either blunt or penetrating trauma and involves continuous air flow from the trachea, bronchi, or chest wall into the pleural space, causing a shift of the mediastinum, deviation of the trachea away from the tension, respiratory distress, increased intrathoracic pressures, decreased venous return, hypotension, and, ultimately, shock if unrecognized and untreated. Managing a pneumothorax includes inserting a chest tube. A hemothorax is the collection of blood in the pleural space caused by blunt or penetrating trauma and can lead to mediastinal shift, respiratory distress, and hypovolemic shock, prompting emergency management with tube thoracostomy and transfusion and immediate surgery.\(^3\)

Circulation with Hemorrhage Control

One of the main concerns in the trauma patient is uncontrolled bleeding, which can lead to hemorrhagic shock and, if not detected and treated early, death secondary to organ hypoperfusion. Locations of hemorrhage include thoracic cavity, abdominal cavity, pelvic fracture (retroperitoneum), and long bones or obvious external bleeding.\(^3\) Clinical assessment of hypovolemic shock secondary to hemorrhage includes parameters such as heart rate, pulse pressure, urine output, skin color, temperature, and mental status. Hemorrhagic shock is broken into four classes, based on estimated blood loss (Table 43.1).
Managing hemorrhage in the trauma patient begins with securing two large-bore venous catheters for appropriate fluid resuscitation together with hemorrhage control. Trauma patients with hypovolemic shock can be classified as fluid rapid responders, transient responders, or nonresponders (Table 43.2).

Bleeding control can be done through applying direct pressure on the bleeding vessel for obvious bleeding. For less obvious sources, proximal pressure over the femoral artery in the groin or the brachial artery in the upper extremity can be applied. A hemothorax is managed with insertion of a chest tube and operative control. Intra-abdominal bleeding in the setting of shock requires emergency laparotomy, and a pelvic fracture leading to hemorrhage is treated by pelvic stabilization or extraperitoneal packing.

Disability: Neurological Status

Once the ABCs have been completed, a neurological assessment including GCS score and pupillary examination (including size, symmetry, and reaction to light) is performed. Possible blunt trauma to the brain warrants a computed tomography (CT) scan for further evaluation.

Exposure and Environmental Control

A patient’s clothing should be removed immediately to allow appropriate evaluation; however, it is important to ensure that the patient does not become hypothermic using warmed blankets, fluids, and air. Findings during this part of the assessment will drive further evaluation and intervention.

Adjuncts

Adjuncts to the primary survey include frequent monitoring of oxygenation and ventilation, vital signs, hemodynamics, and neurological status. In addition, a urinary catheter and a nasogastric/orogastric tube are inserted. Diagnostic imaging such as
radiographs and CT scans is ordered as appropriate. The focused assessment with sonography for trauma (FAST) examination helps identify fluid or blood in the pericardial and peritoneal cavity. Four windows are examined using sonography: the pericardium, the spaces between the liver and the kidney (Morison pouch), the spaces between the spleen and the kidney (splenorenal recess), and the space over the bladder. An unstable patient with a positive FAST is transferred emergently to the operating room for definitive control of the hemorrhage.

### Table 44.2 Responses to Initial Fluid Resuscitation

- Crystalloid
- Crystalloid/blood
- Crystalloid and blood
On completion of the primary survey, the decision for early transfer to a more specialized trauma center is made, depending on the patient’s injuries and the available resources.

### Secondary Survey

The secondary survey follows the primary survey once the patient’s ABCs have been stabilized and includes obtaining a medical history and completing a detailed physical examination. On the patient’s arrival to the hospital, prehospital personnel can furnish much of the patient’s history using the mnemonic AMPLE (A – allergies, M – medications currently used, P – past illness/pregnancy, L – last meal, E – events/environment related to injury). The patient should always be asked about tetanus status.

The physical examination includes a complete assessment from head to toe, including the head and face, neck and spine, chest, abdomen, and musculoskeletal and peripheral vascular systems. The neurological examination includes a motor and sensory examination, and patients with altered consciousness should have a CT scan of the brain.

Adjuncts to the secondary survey include routine radiography and angiography, among others. Laboratory results should be reviewed, including base deficit and lactate concentrations, which are markers of...
hypoperfusion.

After completing the secondary survey, continuous reassessment of the patient is essential. If there is any clinical worsening, steps of the primary survey are repeated.

**INITIAL MANAGEMENT**

**Physiology of Hypovolemic Shock**

Hypovolemic shock is a state of inappropriate delivery of oxygen and nutrients to organs secondary to volume loss. Hallmarks of hypovolemic shock include hypoperfusion secondary to an unbalanced oxygen demand and supply at the cellular level. This leads to cellular injury, which initially can be reversible but can progress to irreversible damage if not recognized and managed early enough. Hemorrhagic shock is a type of hypovolemic shock secondary to blood loss. During early hemorrhagic shock, compensatory mechanisms including neuroendocrine and cardiovascular responses are activated to maintain hemodynamics and perfusion.\(^{10}\) As the bleeding continues, however, compensatory mechanisms fail, and the patient goes into cardiovascular collapse. Decompensated hypovolemic shock leads to multiorgan dysfunction, inflammation, and microcirculatory shock. Once parenchymal and microvascular injury has ensued, volume resuscitation strategies cannot reverse the process. Reperfusion injury can further worsen the initial insult. If decompensated hemorrhagic shock is left untreated, the outcome can be fatal.

Non-trauma causes of hemorrhagic shock include antithrombotic therapy, coagulopathies, gastrointestinal (GI) bleeding, and a ruptured aneurysm. Pulmonary etiologies include lung cancer and cavitary lung disease, whereas obstetric/gynecologic causes include ruptured ectopic pregnancy, ruptured ovarian cyst, and placenta previa, among others. In the trauma patient, hemorrhage can be external and visible or can be internal. Lacerations, penetrating trauma (e.g., gunshot wounds), blunt trauma, and ruptured major vessels can all lead to life-threatening hemorrhage.\(^{11}\)
A 70-kg patient is composed of 60% total body water (42 L), which can be further divided into 28 L of intra-cellular water (2 L of red cell volume and 26 L within muscles and organs) and 14 L of extracellular water (3 L of plasma volume and 11 L of interstitial space fluid, which mostly comprises the interstitial space matrix). The average adult blood volume is 7% of body weight, which is about 5 L in a 70-kg patient.\textsuperscript{12}

There are four classes of hemorrhagic shock (classes I–IV), based on blood loss (Table 43.1). The physiology of hemorrhagic shock consists of three phases. Phase I describes the state of shock and active hemorrhage (from admission to the end of surgery/definitive bleeding control). Phase II is the obligatory extravascular fluid sequestration phase from the end of surgery to the time of maximal weight gain. Phase III describes the time during which fluid mobilization and diuresis occur (from maximal weight gain to positive fluid balance).\textsuperscript{12}

**Management of Hemorrhagic Shock: Fluid Resuscitation**

The goals of managing hemorrhagic shock are to stop the bleeding and to restore hemodynamics to minimize hypoperfusion and associated ischemic damage to all organs. Management of hemorrhagic shock starts with establishing vascular access for fluid and blood resuscitation, which is accomplished by inserting at least two short, large-bore intravenous catheters.\textsuperscript{10,13} Intravenous fluid resuscitation is an important strategy in restoring intravascular volume.

**Resuscitation Goals**

The aim of trauma resuscitation is to restore normal hemostasis by addressing shock and the resulting oxygen debt.\textsuperscript{14} Oxygen debt is evaluated by monitoring either serum lactate or base deficit. The goal of trauma resuscitation is the normalization of either parameter.\textsuperscript{15} Available resuscitation fluids include crystalloids (0.9% sodium chloride solution [“normal saline”], lactated Ringer, Plasmalyte [“balanced
crystalloid”]) and colloids (albumin [4%–25%], hydroxyethyl starches, gelatin solutions). Classically, lactated Ringer has been the resuscitation fluid of choice for trauma resuscitation, but other fluids have been used as well, with varying efficacy and safety profiles.

**Plasmalyte**

Plasmalyte is a balanced crystalloid solution with different available formulations, designed to mimic human plasma. It can be used for fluid resuscitation (filling the intravascular space) or fluid replacement (extravascular deficit). Plasmalyte is different from lactated Ringer because it contains acetate as a buffer instead of lactate, which theoretically reduces carbon dioxide production. A theoretical concern with the use of Plasmalyte in trauma resuscitation is that it contains magnesium, which has undesirable hemodynamic effects (bradycardia, decreased peripheral vascular resistance). To date, only one study has evaluated its use in trauma resuscitation.

Young et al. compared resuscitation with normal saline with resuscitation with Plasma-Lyte A, a calcium-free balanced crystalloid solution, in adult trauma patients (n=46) requiring blood transfusion and operative management within 60 minutes of hospital arrival and found that the mean base excess improvement from 0 to 24 hours, the primary outcome of the study, was significantly greater with Plasma-Lyte A (7.5 ± 4.7 vs. 4.4 ± 3.9 mmol/L; difference 3.1 [95% confidence interval {CI}, 0.5–5.6]; p = not available), with a higher pH at 24 hours (7.41 ± 0.06 vs. 7.37 ± 0.07; difference 0.05 [95% CI, 0.01–0.09]) and a lower chloride concentration at 24 hours (104 ± 4 vs. 111 ± 8 mEq/L; difference -7 [95% CI, -10 to -3]). There were no differences in the volumes of fluids administered, 24-hour urine output, resource use measures, or mortality.

Although the concept of balanced resuscitation fluids with a physiology similar to human plasma is appealing and the clinical evidence in trauma is promising, more studies are needed to validate use in this population.
Colloids

Colloids are suspensions of molecules within a carrier solution, usually incapable of crossing a healthy semipermeable capillary membrane because of their molecular weight. The use of colloids is supported by the rationale that they can expand the intravascular volume and maintain colloid oncotic pressure without causing fluid overload. This volume-sparing effect is traditionally thought to be in a 1:3 ratio of colloids to crystalloids to replete intravascular depletion.

Different colloids are available, including human albumin and semisynthetic colloids including hydroxyethyl starches, gelatin products, and dextrans. Albumin is considered the reference colloid. Hydroxyethyl starch is produced by hydroxyethyl substitution of glucose molecules from maize, potatoes, or sorghum. This substitution leads to protection against hydrolysis and, hence, a prolonged intravascular volume expansion; however, it also increases the risk of accumulation in different tissues such as the skin, liver, and kidneys.

Theoretically, semisynthetic colloids are a good alternative to costly albumin because they are good volume expanders, can be manufactured cheaply, and do not bear the risk of bloodborne infections; however, they have been shown to accumulate in different organs, causing adverse effects. In addition, high-molecular-weight hydroxyethyl starch products can cause coagulopathies. The use of hydroxyethyl starch solutions with molecular weights greater than 200 kD and a molar substitution ratio of more than 0.5 has been linked to higher rates of mortality, acute kidney injury (AKI), and renal replacement therapy use in patients with sepsis. The recommended maximal daily dose of hydroxyethyl starch is 33–50 mL/kg.

Albumin

The SAFE trial, a multicenter, randomized, double-blind study, assessed the use of 4% albumin versus normal saline for intravascular fluid resuscitation in a mixed intensive care unit (ICU) patient population (43% surgical admissions vs. 57% medical admissions) and found no difference in 28-day mortality (relative risk [RR] of death 0.99; 95% CI,
0.91–1.09; p=0.87), new single-organ and multiorgan failure (p=0.85), ICU (p=0.44) or hospital length of stay (p=0.30), days of mechanical ventilation (0.74), or days of renal replacement therapy (p=0.41). In a subgroup analysis of patients admitted with trauma, the albumin-receiving group had a trend toward higher 28-day mortality than the saline-receiving group (13.6% vs. 10.0%; p=0.06).

The SAFE trial investigators conducted a further post hoc analysis specifically targeting patients with a traumatic brain injury (TBI) because of concern for increased mortality in the albumin group. This group of patients had an increased 24-month mortality if they had received albumin (33.2% vs. 20.4%; RR 1.63; 95% CI, 1.17–2.26; p=0.003). The effect was attributed to increased intracranial pressure (ICP).

The CRISTAL study, a multicenter, randomized, open-label trial (with investigators blinded to treatment assessment), included 2,857 patients from different ICUs receiving colloids (including gelatins, dextrans, hydroxyethyl starches, and 4% or 20% albumin) versus crystalloids (iso-tonic or hypertonic saline or lactated Ringer) for hypovolemic shock. Seventy percent of patients were admitted to the ICU because of medical diagnosis, followed by about 20% admitted secondary to an emergency surgery (6.2%–7.8% admitted because of a scheduled surgery and 1.6%–2.5% admitted secondary to trauma). The primary outcome, 28-day mortality, did not differ between groups (25.4% in colloids vs. 27.0% in crystalloids; RR 0.96 [95% CI, 0.88–1.04]; p=0.26); however, 90-day mortality was higher in the crystalloid group (34.2% in crystalloids vs. 30.7% in colloids; RR 0.92 [95% CI, 0.86–0.99]; p=0.03). Other secondary outcomes, including the number of days alive without mechanical ventilation and without vasopressors at days 7 and 28, were all higher in the colloid group.

In a recent study evaluating the effects of intraoperative use of colloids on postoperative fluid needs, non-colloids (balanced electrolyte solution) plus low fresh frozen plasma (FFP)/red blood cell (RBC) ratio resuscitation (0.35 or less) were compared with the administration of colloids (human albumin) plus high FFP/RBC ratio resuscitation (greater than 0.35). Administering albumin and high FFP/RBC resuscitation did
not prevent phase II fluid uptake (fluid sequestration phase). In contrast, it caused a decrease in urine output despite increased plasma volume. The authors theorized that colloids reduce glomerular filtration and increase tubular reabsorption, thus increasing extracellular fluid and prolonging phase II.

**Hydroxyethyl Starches**

The Crystalloid versus Hydroxyethyl Starch Trial (CHEST), with 42% of patients admitted after surgery and 8% trauma patients, randomized patients 1:1 to either 6% hydroxyethyl starch (molecular weight 130 kD and molar substitution ratio of 0.4) or normal saline for fluid resuscitation and found no 90-day mortality difference (18% in hydroxyethyl starch group vs. 17% in normal saline group; 95% CI, 0.96–1.18; p=0.26). More patients in the hydroxyethyl starch group required renal replacement therapy (7% vs. 5.8% in saline group; RR 1.21; 95% CI, 1.00–1.45; p=0.04), and more patients in the hydroxyethyl starch group developed renal injury (according to the RIFLE criteria) (7% vs. 5.8%; RR 1.21; 95% CI, 1.00–1.45; p=0.04). The use of hydroxyethyl starch was also associated with more adverse events such as pruritus and rash (5.3% vs. 2.8%, p<0.001).

In a recent meta-analysis evaluating outcomes with the use of hydroxyethyl starch for fluid resuscitation in a heterogeneous patient population including patients with trauma, sepsis, hypovolemic shock, and burns after excluding some biased trials, hydroxyethyl starch was associated with increased mortality (RR 1.09; 95% CI, 1.02–1.17), increased renal failure (RR 1.27; 95% CI, 1.09–1.47), and increased use of renal replacement therapy (RR 1.32; 95% CI, 1.15–1.50). Therefore, the use of hydroxyethyl starch is no longer recommended because of serious safety concerns.

Given the evidence, crystalloids remain the main fluid of choice for resuscitation. In patients without head injury, albumin may be considered if the patient becomes fluid overloaded and continues to have intravascular depletion.
Trauma-Induced Coagulopathy

Trauma-induced coagulopathy (TIC) is “nonsurgical” bleeding from serosal surfaces, mucosal lesions, and wound sites. Classically, TIC has been attributed to the dilutional effects of crystalloid and packed red blood cell (PRBC) resuscitation; however, research has revealed the presence of TIC, even in patients who had received very little resuscitation. Accordingly, the focus has shifted from restoring circulating volume by intravenous fluid and RBCs to the concept of hemostatic resuscitation.

Of note, the incidence of TIC immediately after traumatic injury is quite high (24%–28%), contrary to the traditional belief that this is a later complication of trauma. The evolution of TIC occurs in three phases. The first phase constitutes the immediate activation of hemostatic pathways, including fibrinolysis and thrombosis associated with tissue injury. During the second phase, the patient receives resuscitation fluids and blood products, which lead to dilution of hemostatic factors. Phase 3 is the post-resuscitation phase, where a prothrombotic state prevails.

During TIC, there is a large consumption of coagulation factors and platelets secondary to the formation of thrombi and extravascular clots. Platelet migration to the injured vessel wall is interrupted once the hematocrit falls below 30%. Part of the resulting coagulopathy is dilutional because of large volumes of intravenous fluids and blood products. Hormonal and cytokine changes lead to endothelial cell activation, which in turn results in changing the endothelial cell from antithrombotic to prothrombotic, a phenomenon that can lead to DIC (disseminated intravascular coagulopathy).

The combination of hypoxia, hypothermia, and acidosis has been termed the bloody vicious triad or lethal triad because of its deleterious effects in hypotensive trauma patients with TIC. Hypoxia, commonly seen in the hypoperfused trauma patient in hemorrhagic shock, exacerbates endothelial cell activation. Hypothermia, defined as a core body temperature less than 35°C, is a result of convection, radiation, wet clothing, insensible fluid losses from open wounds and surgical incisions, and resuscitation with crystalloids at room temperature or
cold PRBCs. The consequences of hypothermia include impaired platelet activation and adhesion, together with increased sequestration by the liver. Hypoperfusion leads to anaerobic metabolism, which results in acidosis. Coagulopathies are more pronounced when core temperature falls below 33°C and pH falls below 7.1.

The diagnosis of TIC is based on laboratory values such as prothrombin time (greater than 1.5 times normal), activated thromboplastin time (greater than 1.5 times normal), an international normalized ratio (INR) greater than 1.5, thrombocytopenia (platelet count less than 50,000/mm$^3$), and low fibrinogen concentration (less than 0.5–1 g/L). Of note, these values do not account for dysfunctional platelets or hyperfibrinolysis.

Management of TIC is based on the concept of damage control resuscitation, which entails minimizing crystalloid resuscitation, allowing hypotension until arrival to the operating room, preventing coagulopathy through the early administration of blood products in a balanced ratio (massive transfusion protocol [MTP]), and addressing the acidosis, coagulopathy, and hypothermia associated with TIC.

Resuscitation Volume

How much fluid resuscitation to provide the trauma patient is an important question to ask because more is not always better. Over-resuscitation is associated with concerns for increased tissue edema leading to complications such as the abdominal compartment syndrome, anastomotic leaks, acute coronary syndromes, and acute respiratory distress syndrome. There can also be increased bleeding from dislodged clots, a dilutional coagulopathy, and exacerbated hypothermia.

The American College of Surgeons Committee on Trauma and the subcommittee and the international Advanced Trauma Life Support working group promote the concept of balanced resuscitation instead of aggressive resuscitation. This can be achieved through the standard administration of warmed 1 L of crystalloids (lactated Ringer or 0.9% sodium chloride solutions) as a starting point instead of the previously recommended 2 L. The group also suggests the use of
blood products.

In 1994, Bickell et al. published the results of a study evaluating patients with penetrating torso trauma with a prehospital systolic blood pressure of 90 mm Hg or less. Patients were randomized to receive traditional fluid resuscitation or delayed resuscitation in the field and emergency department before arrival to the operating room for definitive bleeding management. Patients in the delayed fluid group received intravenous cannulation and no more than 100 mL before surgical intervention, and they had a survival benefit (70% vs. 62%; p=0.04), fewer complications, and a shorter hospital length of stay.

In a recent systemic review of 11 studies comparing liberal with restricted fluid resuscitation strategies in major trauma patients (defined as an injury severity score [ISS] of 16 or greater), there was an increase in mortality in the four included randomized trials (RR 1.18; 95% CI, 0.98–1.141) and in the seven included observational studies (odds ratio [OR] 1.14; 95% CI, 1.01–1.28) for patients who received a liberal fluid resuscitation strategy.

Most of the available evidence for clinical benefit with hypotensive resuscitative strategies exists for penetrating trauma, with evidence lacking for other forms of trauma; therefore, the generalizability of this strategy remains controversial.

Massive Transfusion

In general, blood transfusion during hemorrhage is indicated in patients with a blood loss of 30% or greater (class III hemorrhage). In addition, a hypotensive patient who does not respond to a 1- or 2-L crystalloid challenge should be considered for a blood transfusion. Massive transfusion is defined by administration of greater than 10 units of PRBCs in a 24-hour period. The goal of an MTP is to standardize the blood products the patient is receiving and to optimize quick access to the blood products needed. An example of an MTP is the combination of 6 units of FFP, 6 units of PRBCs, 6 packs of platelets, and 10 units of cryoprecipitate.

There has been a shift from aggressive PRBC trans-fusion to transfusion of a standardized ratio of PRBCs/FFP/platelets because
large amounts of PRBCs have been associated with negative outcomes, given recent military experience. In a retrospective evaluation, Borgman et al. found that trauma patients in the military who received a low FFP/PRBC ratio (1 unit of plasma to 8 units of PRBCs) had the highest mortality (65%) and that mortality decreased as the ratio became more balanced (34% mortality for a 1:2.5 ratio and 19% mortality for a 1:1.4 ratio).\textsuperscript{36} The authors attributed these results to trauma-induced coagulopathies, which could be attenuated with increased transfusion of FFP.

Similar results were seen in a retrospective study evaluating a civilian trauma population that had received massive transfusion. Higher 30-day survival was associated with a higher plasma/PRBC ratio (1:2 or greater) than with a low plasma/RBC ratio (less than 1:2) (survival of 59.6% vs. 40.4%; \(p<0.01\)). The same observation was made for the platelet/RBC ratio (higher survival of 59.9% in the high-ratio group [1:2 or greater] vs. 40.1% in the low-ratio group [less than 1:2]).\textsuperscript{37} Despite their potential significant influence on trauma resuscitation, both studies were criticized for their retrospective design and concern for survival bias (i.e., only patients who survive can receive more blood products, altering the ratio of blood products received).

In the recently published PROPPR trial (transfusion of plasma, platelets, and RBCs in a 1:1:1 vs. a 1:1:2 ratio and mortality in patients with severe trauma), severely injured patients with hemorrhagic shock were randomized to receive plasma, platelets, and PRBCs in a 1:1:1 ratio or a 1:1:2 ratio, in addition to all the uncontrolled local standard of care therapies, at the 12 participating level I trauma centers.\textsuperscript{38} The primary outcome, all-cause mortality at 24 hours and at 30 days, was no different between the groups (24-hour mortality: 12.7% in 1:1:1 group vs. 17.0% group in 1:1:2 group; \(p=0.12\), and 30-day mortality: 22.4% in 1:1:1 group vs. 26.1% in 1:1:2 group; \(p=0.26\)); however, exsanguination, the primary cause of death within the first 24 hours, was significantly lower in the 1:1:1 group (9.2% vs. 14.6% in 1:1:2 group; \(p=0.03\)). More patients in the 1:1:1 group achieved hemostasis within the first 24 hours (86% vs. 78% in the 1:1:2 group; \(p=0.006\)). No increased complications were seen in the 1:1:1 group, despite
Triggers for initiating an MTP should be defined to allow rapid identification of trauma candidates because this has been shown to improve mortality as well as prevent patients without massive bleeding from receiving an MTP inappropriately.

The current indication for an MTP is the need to transfuse 6–10 units of PRBCs. Other clinical triggers may include multicavitary trauma, penetrating trauma, low hemoglobin, and free fluid present on the FAST examination.³⁹

**Components of MTP**

**Packed Red Blood Cells**

Packed red blood cells are prepared by removing plasma from whole blood. One unit of PRBCs comes in a volume of 200–350 mL, and administration of 1 unit is usually expected to raise hemoglobin concentrations by 1 g/dL. Packed red blood cells not only help with oxygen transport, but are also thought to improve hemostasis by inducing platelet margination (migration of platelets to the injured epithelium wall).²⁴ Packed red blood cells lose some of their clinical effects during storage.

**Fresh Frozen Plasma**

Fresh frozen plasma can be separated from whole blood or obtained from donors by plasmapheresis and is stored at a temperature below 30°C. It contains proteins involved in hemostasis, including coagulation factors, anticoagulation proteins, and fibrinolysis proteins. Fresh frozen plasma pack volumes are usually between 150 mL and 250 mL. Trauma patients receive FFP therapy if they have active bleeding together with a prothrombin time or activated partial thromboplastin time (aPTT) greater than 1.5 times normal or if the INR is greater than 1.5 (dosed at 10–15 mL/kg).²⁴

**Platelets**

Platelets, which are separated from whole blood by centrifugation or apheresis, can remain at room temperature for about 5 days. Platelets may need to be supplemented in trauma because of platelet consumption or a dysfunctional state during the acute phase. Patients with platelet counts less than 50,000 mm$^3$ or those with a TBI and a platelet count less than 100,000 mm$^3$ should receive platelets. Transfusing 1 unit of platelets is thought to increase the platelet count by 20,000. Patients who had been receiving antiplatelet medications such as aspirin or P2Y$_{12}$ inhibitors will have increased PRBC and platelet requirements.\textsuperscript{24}

Fibrinogen

Fibrinogen, a plasma protein produced in the liver, is converted to fibrin during clot formation and is the first coagulation factor to become deficient during massive blood loss, necessitating replacement if concentrations fall below 0.8–1 g/L.\textsuperscript{24} Fresh frozen plasma contains some fibrinogen as part of its coagulation factors; however, if fibrinogen concentrations are still not corrected, cryoprecipitate is administered. Cryoprecipitate is a blood product obtained from donors and prepared from plasma and contains different factors including fibrinogen, von Willebrand factor, fibronectin, and factors VIII and XIII. The fibrinogen concentration is expected to increase by 0.5 g/L for each dose of cryoprecipitate (dosed in 1 unit/10 kg; each dose about 8–10 units).

**Pharmacologic Adjuncts**

In addition to blood product transfusion, some adjuncts are used to restore hemostasis, including recombinant human factor VIIa, prothrombin complex concentrate, and antifibrinolytics such as tranexamic acid and aminocaproic acid.

**Recombinant Human Factor VIIa**

Recombinant human factor VIIa is indicated for the treatment of hemophilia. It works by activating platelet adhesion at the site of injury.
and has been evaluated in a study with blunt trauma patients, where it led to a decrease in PRBC transfusion and the need for MTPs.\textsuperscript{40} A follow-up paper by the same group showed a decrease in multiorgan failure and acute respiratory distress syndrome; however, neither study showed improved survival.\textsuperscript{41}

Other studies, including the large multicenter CONTROL trial, showed no survival benefit.\textsuperscript{42} In addition, there remains the concern for thromboembolic events with the administration of factor VIIa. Given the concerns for thrombosis and the lack of survival benefit, factor VIIa use for trauma remains off-label and is not recommended as part of damage control resuscitation.

Prothrombin Complex Concentrate

Prothrombin complex concentrate contains different coagulation factors. The three-factor prothrombin complex concentrate products such as Bebulin and Profilnin SD contain factors II, IX, and X, whereas the four-factor products such as Kcentra and Octaplex contain factors II, VII, XI, and X and proteins S and C.\textsuperscript{43-46} Compared with coagulation factor replacement with plasma, prothrombin complex concentrate products are thought to cause less volume overload, carry a lower risk of transfusion reactions, and be easier and faster to prepare than plasma, which requires an ABO type and screen, and thawing before transfusion. Prothrombin complex concentrate has mainly been studied for the reversal of bleeding secondary to anticoagulants, namely warfarin. There is some published evidence on its use in trauma patients comparing prothrombin complex concentrate with FFP. Despite no improvement in survival, a decrease in need for PRBC transfusion and in multiorgan failure was seen, together with a shorter mechanical ventilation time and hospital length of stay.\textsuperscript{47}

Antifibrinolytics

Tranexamic acid, a commonly used antifibrinolytic agent, is a synthetic derivative of lysine.\textsuperscript{39} It inhibits fibrinolysis by binding to the lysine site, inhibiting plasminogen activation and plasmin activity. The CRASH-2 trial was a randomized controlled trial performed in 274 hospitals.\textsuperscript{48}
More than 20,000 adult trauma patients with significant bleeding were randomly assigned within 8 hours of injury to receive either tranexamic acid (loading dose of 1 g over 10 minutes, followed by infusion of 1 g over 8 hours) or the matching placebo. All-cause mortality was significantly lower in the tranexamic acid group (14.5% vs. 16.0%; RR 0.91; 95% CI, 0.85–0.97; p=0.0035), and the risk of mortality secondary to bleeding was decreased as well (4.9% in the tranexamic acid group vs. 5.7%; RR 0.85; 95% CI, 0.76–0.96; p=0.0077). There were no statistically significant differences in thromboembolic events. The quoted benefit was only evident if tranexamic acid was administered within the first 3, with later administration leading to an increase in mortality.49

Morrison et al. investigated the use of tranexamic acid in military trauma patients in the Military Application of Tranexamic Acid in Trauma Emergency Resuscitation (MATTERs) study. This was a retrospective observational trial comparing patients who had received tranexamic acid with those who had not, as well as the subgroup of patients who required massive transfusion, defined as 10 units or greater of PRBCs.50 Patients who received tranexamic acid had a lower unadjusted mortality than those who did not (17.4% vs. 23.9%; p=0.03), despite being more severely injured (mean [SD] ISS 25.2 [16.6] vs. 22.5 [18.5]; p<0.001). This benefit was more pronounced in the subgroup that required massive transfusion. A multivariate regression analysis found tranexamic acid to be an independent predictor of survival.

The MATTERs II study, published in 2013, retrospectively compared four groups of military trauma patients: the tranexamic acid/cryoprecipitate group, the tranexamic acid group, the cryoprecipitate group, and the patient group that received neither therapy.51 Patients who had received both cryoprecipitate and tranexamic acid had the lowest mortality (11.6%) compared with the tranexamic acid group (18.2%) and the cryoprecipitate group (21.4%), despite higher ISS values and higher PRBC requirements, whereas the group that received neither therapy had the highest mortality rate (23.6%).
ORGAN-SPECIFIC INJURIES

Blunt Cerebrovascular Injuries

Epidemiology and Pathophysiology

Although once thought to be uncommon, blunt cerebrovascular injuries (BCVIs) are becoming increasingly recognized and detected. Data from a recent publication that evaluated the NIS (Nationwide Inpatient Sample), which is the largest all-payer hospital inpatient database in the United States, show that from 2003 through 2010, 1,283–2,652 patients were admitted annually for BCVI. This represented 0.46%–0.95% of all blunt trauma admissions, with the annual nationwide incidence increasing over time. Blunt cerebrovascular injury is a devastating complication of trauma with an associated mortality rate of 40% and neurological comorbidity of up to 80%. Blunt cerebrovascular injury is defined as a wall injury in the vertebral or carotid artery caused by nonpenetrating trauma. The general mechanisms behind BCVI are related to hyperextension and rotation, hyperflexion, or a direct blow to the neck. The resultant damage to the intimal layer of the artery results in exposure of the subendothelial collagen. This stimulates platelet aggregation as well as activation of the clotting cascade, resulting in thrombin generation and subsequent thrombosis. One of the challenges with BCVI is that the neurological symptoms, particularly stroke, present in a latent manner with a time from injury to symptom onset of 10–72 hours, on average. It is important that early screening be conducted to promptly identify and treat these patients during this latent period before potentially irreversible complications occur. To this end, criteria for the screening of these patients were initially proposed by Biffl et al. in 1999 and later modified in 2004 to create the Denver criteria. Risk factors highlighted by the Denver criteria involve high-energy transfer mechanisms with the following associated injuries: (1) Le Fort II or III fractures; (2) cervical spine fracture patterns such as subluxation, fractures extending into the transverse foramen, and fractures of C1–C3; (3) basilar skull fractures with carotid canal involvement; (4) diffuse
axonial injury with a GCS score of 6 or less; and (5) near hanging with anoxic brain injury.\textsuperscript{59} Once identified, such patients should have their cerebral vasculature evaluated by four-vessel cerebral angiography (“gold standard”) or CT angiography.\textsuperscript{60} The severity of BCVI is graded using the following scale proposed by Biffl et al.\textsuperscript{61}

- Grade I – intimal irregularity with less than 25% narrowing
- Grade II – dissection or intramural hematoma with greater than 25% narrowing
- Grade III – pseudoaneurysm
- Grade IV – occlusion
- Grade V – transection with extravasation

**Management**

Management of BCVI can involve anticoagulation, surgical intervention, or endovascular repair (with antiplatelet therapy). Most data evaluations for surgical intervention are from retrospective studies conducted more than 20 years ago and suggest that revascularization is beneficial in patients without neurological deficits compared with ligation.\textsuperscript{62-66} With the growing experience in anticoagulation and advances in endovascular technology, the surgical approach has fallen out of favor. Antithrombotic therapy with heparin (goal of aPTT of 40–50 seconds) and transition to warfarin has historically been the gold standard for managing BCVI, as supported by several papers.\textsuperscript{67-73} Of these, only one paper has shown significant neurological improvement with antithrombotic management.\textsuperscript{69} The challenge with managing with heparin in particular is the added risk of hemorrhage with this therapy. Biffl et al. noted a 54% hemorrhage risk in their paper requiring transfusions and/or cessation of heparin therapy.\textsuperscript{71} Despite the goal aPTT of 60–70 seconds at their institution, all the patients who bled had a mean maximum aPTT well outside the range at 87.2 seconds. The paper published by Parikh et al. had a target aPTT of 50–60 seconds and noted a 40% (6 of 15) significant hemorrhage risk in their
patients. In Memphis, Fabian et al. documented a 13% (6 of 47) bleeding risk when a goal aPTT of 40–50 seconds was used. Although the risk of hemorrhage was lower with the lower aPTT goals, the lack of standardized aPTT levels, together with heparin's complex pharmacokinetic and pharmacodynamic properties, makes it a challenging drug to dose. Moreover, 25% of the patients in the Memphis study could not receive anticoagulation with heparin for various reasons. The clinical dilemma is that systemic heparin appears to be beneficial for managing BCVI, but there is an added risk of hemorrhage or inability to initiate heparin therapy for one or more relative or absolute contraindications (TBI, recent surgery, solid organ hematoma, etc.).

Challenges with heparin therapy have forced clinicians to explore the role of antiplatelet therapy in treating these patients. In a retrospective analysis of 22 patients for an 8-year period, Wahl et al. evaluated 14 patients who received anticoagulation for BCVI, with seven receiving systemic heparin (goal aPTT of 40–60 seconds) and seven receiving aspirin. All but one survived in each group with fair to good neurological examinations. Four of the seven patients receiving heparin developed significant bleeds requiring discontinuation of heparin and blood transfusions versus none in the aspirin group, which was statistically significant (p<0.05). Cothren et al. published their Denver experience of more than 400 patients in two studies and showed similar benefits of antiplatelet agents over heparin. Although the authors concluded that both systemic heparin and either monotherapy or combination antiplatelet therapy are equivalent, a caveat was that the systemic heparin group had more grade II, III, and IV injuries. Morton et al. more recently published their experiences with antiplatelet therapy in severe BCVI, where all grade IV injuries (typically have contraindications to heparin) received aspirin as part of routine care, with the addition of clopidogrel in those with carotid artery involvement. The authors reported a stroke rate of about 17% (10 of 59) versus reports of 40%–80% in untreated patients, showing the benefits of antiplatelet therapy in this high-risk population. The challenge with the data comparing the efficacy of antiplatelet therapy
with that of antithrombotic therapy is the lack of high-quality trials comparing these two therapies directly, which is highlighted in the Eastern Association for the Surgery of Trauma guidelines. These suggest that the evidence supports using antithrombotic therapy in those with no contraindications and reserving antiplatelet therapy for all others. In addition to selecting the appropriate anticoagulant, therapy duration has not been well defined in the published literature, and only one study has discussed this issue to date. Biffl et al. evaluated 179 patients with BCVI who received repeat arteriography 7–10 days from the initial diagnosis. Data showed that 57% of grade I and 8% of grade II injuries healed, allowing antithrombotic therapy to be discontinued, whereas 93% of grade III and 82% of grade IV injuries remained unchanged. Of note, 8% of grade I and 43% of grade II injuries progressed to pseudo-aneurysms requiring intervention. This study highlighted the need for reimaging in order to adjust therapy according to the patient’s response as well as potentially longer anticoagulation periods for more severe BCVI. Two additional studies evaluated long-term outcomes (mean follow-ups of 22 and 29 months) in BCVI; however, neither addressed the duration of anticoagulation.

Endovascular therapy is an attractive option in treating patients with contraindications to anticoagulant therapy or with higher-grade lesions. This is particularly true in grade III lesions where pseudoaneurysms weaken the vascular wall, setting the stage for devastating complications if left untreated. To date, three papers have evaluated outcomes related to endovascular repair. The first paper, by Cothren et al., evaluated 46 patients with BCVI over an 8-year period (1996–2004), of whom 23 received antithrombotic therapy alone and 23 received endovascular stenting together with antithrombotic therapy. The authors reported a complication rate of 21% (4 of 18) and a reocclusion rate of 45% (8 of 18) versus no complications in the 23 patients who did not receive stents, with one patient developing thrombosis. The authors recommended against the use of stents as a result of this study, although they did highlight that patients with stents did not receive antiplatelet therapy, which could have been a risk factor.
for reocclusion. Since then, two additional studies have been published with more positive findings. In the paper by Edwards et al., 55 patients who were alive at discharge and had long-term follow-up (mean 29 months) data were evaluated, of whom 41 received antithrombotic or anti-platelet therapy, whereas 14 received endovascular repair.\textsuperscript{79} None of the patients in either group had a stroke after discharge, and the stents were patent on repeat angiography at a mean of 33 weeks. The final study by DiCocco et al. evaluated 222 patients with BCVI for 53 months. Endovascular repair for BCVI was used in 80 patients (41%), whereas medical management was used in 122 patients (59%).\textsuperscript{80} Three strokes were present in each group after a mean follow-up of 22 months, and the authors concluded that the outcomes between both groups were similar, despite the more grade III injuries in the endovascular group (56 vs. 7). These studies support the use of endovascular repair as a mode of management for BCVI, with outcomes comparable with those of anticoagulant therapy alone.

In conclusion, anticoagulation plays a pivotal role in managing BCVI, with data analyses suggesting that both antithrombotic and antiplatelet therapy are reasonable therapeutic options, though the therapy duration remains undefined. Although the Eastern Association for the Surgery of Trauma guidelines suggest antithrombotic therapy as the preferred mode, challenges with heparin therapy have led more clinicians to use antiplatelet therapy instead. Endovascular repair should be reserved for patients with contraindications to anticoagulation.

\textbf{Traumatic Brain Injury}

\textbf{Pathophysiology and Treatment}

Traumatic brain injury is the disruption or alteration of brain function caused by external forces and represents heterogeneous disease that can occur through a variety of mechanisms and can vary in severity and duration.\textsuperscript{82}

In addition to the primary TBI caused by trauma, secondary injury
may develop hours to days after the initial injury. Pathophysiologic changes that occur include neurotransmitter release, free-radical generation, calcium-mediated damage, mitochondrial dysfunction, and inflammatory responses leading to cell necrosis, apoptosis, and autophagy.\textsuperscript{83-86} The goal of the critical care practitioner in this setting is to prevent or minimize secondary injury as a result of the evolution of the TBI. The two main goals that should be instituted in the prehospital setting to prevent secondary injury are the avoidance of hypotension (systolic blood pressure less than 90 mm Hg) and hypoxia (Pao\textsubscript{2} of 60 mm Hg or less), as noted in the pivotal paper by Chesnut et al.\textsuperscript{87} In this paper, the presence of hypotension and hypoxia increased the mortality rate from 26.9\% to 57.2\% and reduced the percentage of patients with a good or moderate neurological outcome from 53.9\% to 20.5\%. Beyond these fundamental parameters, there has been a significant amount of interest during the past 3 decades to develop “neuroprotective therapies” to reduce secondary brain injury and improve outcomes in patients with TBI. Table 43.3 summarizes the findings of the more recent trials evaluating neuroprotective therapies in TBI. Despite our growing knowledge with respect to the pathophysiology of TBI and the enthusiasm surrounding the results of the early progesterone trials, all therapeutic trials to date have had dismal results. This highlights the complexity of the pathophysiology of TBI and a lack of understanding of the secondary response. As of now, the area of TBI management requires further research.

| Table 43.3 | Summary of Major Clinical Trials Regarding Neuroprotection |
Complications of TBI

Intracranial Hypertension

With no therapies to treat TBI directly, the goal is to manage intracranial hypertension (IH) and seizures. Intracranial hypertension can develop in up to 50% of patients with severe head injury, and persistent elevations are associated with poor outcomes. Intracranial hypertension in TBI is the result of increased intracranial volume because of cerebral edema and hematoma in the cranial vault, which is a fixed-volume space. There are adaptive mechanisms (Monro-Kellie doctrine) such as reducing venous volume and cerebrospinal fluid within the brain that tolerate increases in intracranial volume to a degree; however, when the adaptive capacity is exceeded, IH occurs. Although hemorrhage and hematoma are the result of the trauma causing the TBI, the development of cerebral edema is the result of low ATP (adenosine triphosphate) and subsequent excess intracellular
sodium, calcium, and glutamate (cytogenic) as well as increased microvascular permeability (vasogenic). Management of IH is multi-modal and involves nonpharmacologic interventions such as elevation of the head of the bed, surgical decompression, and extraventricular drainage of cerebrospinal fluid as well as pharmacologic interventions such as pain/agitation control, hyperosmolar therapy, and barbiturate coma. Pain and agitation management practices are covered elsewhere, so this section will focus on hyperosmolar therapy and barbiturate coma.

**Hyperosmolar Therapy**

With cerebral edema being the primary pathophysiologic change that occurs in TBI, treatment with hyperosmotic therapy has become the cornerstone of IH management. Mannitol and hypertonic saline are the two agents routinely used to manage this complication, although data are limited supporting the use of either agent (Table 43.4). Mechanistically, although both create an osmotic gradient, hypertonic saline appears to possess additional hemodynamic, vaso-regulatory, neurochemical, and immunomodulatory properties, though the clinical significance of this difference is unknown. The hemodynamic effects of hypertonic saline have been well shown in several trials. Mannitol has the potential to cause volume depletion in an already low-volume state, whereas hypertonic saline remains in the vascular space. Hypertonic saline provides low-volume resuscitation in addition to its osmotic capabilities, and as such, it has become the preferred agent in managing IH in TBI. A recently published meta-analysis also suggests that, although limited by the small size and number of eligible trials, hypertonic saline is superior to mannitol with respect to ICP control and ICP reductions, which further supports the use of hypertonic saline. However, evidence is weak to support the type or dose of hypertonic saline. Current practice is that hypertonic saline in a continuous infusion or intermittent boluses is administered in patients with TBI to achieve a serum sodium concentration of 145–155 mEq/L; however, there is no evidence to support this practice. The two studies that evaluated the use of hypertonic saline to a target serum sodium showed no response.
of ICPs after 24 hours and worse clinical outcomes. Nonetheless, with the challenges of conducting prospective research in this population, this practice will likely remain standard of care for a significant time. Finally, continuous monitoring of patients while on hyperosmolar therapy is important to mitigate adverse effects. Mannitol carries with it the risk of dehydration, acute renal failure, rebound IH, hypotension, and hypernatremia, whereas hypertonic saline carries the risk of metabolic acidosis, acute renal failure, hypernatremia, hypokalemia, rebound IH, and phlebitis. It is important that frequent monitoring (every 4–6 hours) of serum electrolytes and osmolality be performed to minimize the electrolyte abnormalities and that these therapies be weaned slowly (over 24–48 hours) to minimize the risk of rebound IH. Central pontine myelinolysis is a theoretical concern with hypertonic saline use. No cases have been reported to date; however, to minimize this risk, it is important to avoid serum sodium concentrations greater than 155 mEq/L and serum osmolality greater than 320 mOsm/L and to wean hypertonic saline therapy off slowly.

Barbiturate Coma

Note: The table entries include references to studies which are not presented in the image. The information provided is a summary of the study findings.
When routine sedation and analgesia management and nonpharmacologic options and hyperosmolar therapy fail to control IH, barbiturate coma is used as a last resort, as reflected in the Brain Trauma Foundation guidelines.\textsuperscript{124,125} The mechanism behind barbiturate coma is metabolic suppression leading to reductions in cerebral blood flow and ICP.\textsuperscript{126} Both pentobarbital and thiopental have been used to produce barbiturate coma, with traditional dosing involving several loading doses (10 mg/kg over 30 minutes, followed by 5 mg/kg every hour for three or four doses), followed by a continuous infusion of 1–3 mg/kg/hour, although it is not uncommon to exceed these doses because of the hypermetabolic nature of critically ill trauma patients.\textsuperscript{127,128} Loading doses can also be combined in a 20- to 30-mg/kg single dose administered over 1–2 hours for convenience. Because of the poor correlation between serum or cerebrospinal fluid concentrations and clinical end points, barbiturates are typically titrated either to ICP control or, more routinely, electroencephalography (EEG) burst suppression, therefore requiring continuous EEG monitoring.\textsuperscript{129} In addition, barbiturates are auto-inducers of their own metabolism; therefore, escalating doses may be required to control ICPs or...
maintain burst suppression. Close monitoring of volume status and cardiac function is essential when using barbiturate coma because hypotension and myocardial depression are common adverse effects. Some data suggest that barbiturates also compromise cerebral venous oxygenation in certain patients, resulting in negative clinical outcomes. Therefore, some investigators advocate for invasive cerebral oxygenation monitoring when barbiturates are used, although this is not recommended in the Brain Trauma Foundation guidelines. Additional monitoring for potential propylene-glycol toxicity during long-term or high-dose use with either serum propylene glycol concentrations or more readily available osmolar gap should be considered because this is the excipient in the formulation.

Posttraumatic Seizures

Pathophysiology

Posttraumatic seizures are a common complication of TBI, with an incidence of 11% in severe non-penetrating TBI and up to 35%–50% in penetrating TBI. Traumatic brain injury leads to the disruption of neurons, glial cells, and fiber tracts. This disruption can cause the injured neurons to become hyperexcited, leading to seizures. Risk factors for developing seizures include the presence of a depressed skull fracture, subdural or epidural hematoma, GCS score of less than 10 on presentation, intracerebral hematoma, cortical contusions, and loss of consciousness after the event. Posttraumatic seizures are classified into two categories according to their time of onset: early (within 7 days of injury) and late (more than 7 days after injury). The data analyses available suggest that antiepileptic therapy decreases early seizures but has little effect on late seizures. Early studies evaluating the use of antiepileptic agents in patients with TBI were related to the concern that initial seizures increase the risk of future seizures, based on the kindling phenomenon that has been described in epilepsy. Although an interesting hypothesis, it appears that early seizures are patho-physiologically different from late seizures and, therefore, do not confer any additional risk to the development of long-
term epilepsy. Early seizures appear not to affect clinical outcomes. They can be detrimental in extending secondary injury in patients with severe TBI, however, by elevations in ICP, changes in blood pressure, changes in oxygenation, and so forth. Therefore, preventing early seizures through prophylaxis with antiepileptic agents is a reasonable approach.

Antiepileptic Therapy

Four key studies related to managing early-onset seizures in TBI are reviewed in Table 43.5. Despite some differences in the population demographics, the data overall suggest that prophylaxis for early-onset seizures with either phenytoin or levetiracetam is a reasonable therapeutic option. The lack of significant adverse reactions and drug interactions, ease of dosing, and lower cost have made levetiracetam the preferred agent at many institutions for managing early seizures in patients with TBI.

Spinal Cord Injury

Epidemiology

Spinal injuries are common in trauma patients in the United States. Because of the acutely life-threatening and chronically life-changing consequences of spinal cord injury (SCI), early recognition is very important to guide management and to prevent the progression of secondary injury and further irreversible damage.

Management

The goal of therapy is to stabilize the resulting deficit and to prevent further progression and secondary injury from occurring. Initial treatment of a patient with SCI includes immobilization of the cervical spine in the field, during transport, and during early hospitalization. Airway management is a priority because many of these patients are at risk of hypoxemia from hypoventilation or from aspiration of gastric
Equally important is hemodynamic stabilization because patients with SCI may have loss of systemic sympathetic vasomotor tone after the injury, leading to vasodilation, increased venous capacity, and hypotension, as previously noted.

Surgical management of a patient with SCI is indicated for the unstable spine with or without neurological involvement. Goals of therapy include restoration of spinal stability, correction of spinal alignment, and decompression of affected neurons to permit the best neurological recovery possible. The timing of surgical intervention remains controversial because some clinicians believe that early intervention prevents complications of SCI, whereas others favor delayed surgery to ensure hemodynamic stabilization and decrease the bleeding risk, recognizing that perispinal hematomas organize about 48 hours after injury.

<td>Incidence of early seizure in each group similar (1.5%, p=0.997). The phenytoin group had more adverse reactions and subsequent discontinuation of drug. Levetiracetam group had a longer hospital length of stay (11.8 vs. 7.5 days, p&lt;0.001). All other clinical end points were similar</td>
</tr>
</tbody>
</table>
Although the primary SCI is irreversible, different therapies to limit secondary injury or potentially reverse it have been evaluated over the years. Methylprednisolone, a glucocorticoid thought to reduce injury-induced lipid peroxidation in the spinal cord, was investigated in three large multicenter clinical trials, collectively called the National Acute Spinal Cord Injury Study (NASCIS), which focused primarily on patients with blunt SCI. In 1990, the NASCIS I trial sought to compare a group receiving a 30-mg/kg bolus of methylprednisolone followed by 5.4 mg/kg intravenously for 23 hours’ infusion with a bolus of naloxone 5.4 mg/kg, followed by a continuous infusion of 4 mg/kg/hour, with a placebo group. Naloxone had been postulated to aid in SCI by blocking elevated levels of endogenous endorphins during SCI. A post hoc analysis found an improvement in motor function, sensation to pinprick, and touch in the patient group that had received methylprednisolone within less than 8 hours of injury, whereas treatment with naloxone at any time and treatment with methylprednisolone past the 8-hour mark showed no improvement.\textsuperscript{145} The NASCIS II study published the 1-year follow-up results of the NASCIS I trial and reported an improvement in neurological recovery in patients who had received methylprednisolone within the first 8 hours at 6 weeks, 6 months, and 1 year after injury.\textsuperscript{146}

In the 1997 NASCIS III study, methylprednisolone was compared with tirilazad, an inhibitor of lipid peroxidation, in a double-blind, randomized, multicenter clinical trial.\textsuperscript{147,148} Intravenous methylprednisolone at 30 mg/kg was administered to 499 patients, who were then randomized to receive a 24-hour methylprednisolone infusion at 5.4 mg/kg, a 48-hour infusion at the same rate, or a tirilazad 2.5-mg/kg bolus every 6 hours for 48 hours. The group of patients receiving 48-hour methylprednisolone showed more neurological improvement at 6 weeks and 6 months than the other two groups, and this effect was statistically significant if methylprednisolone was initiated within 3–8 hours of injury.

Despite improvements in American Spinal Injury Association (ASIA) motor and sensory scores in the methylprednisolone groups in the
NASCIS II and NASCIS III trials, the studies had confounders that limit the generalizability of the result. These include missing information concerning radiology, surgical intervention, and rehabilitation. In addition, post hoc analyses have failed to note the neurological improvement reported.\textsuperscript{149-151}

</tbody>
</table>

\textsuperscript{D\textsubscript{5}W} = dextrose 5%; ISS = injury severity score; TPN = total parenteral nutrition.

Of note, the methylprednisolone groups in the NASCIS II and III studies had higher infection rates, in addition to respiratory complications and GI hemorrhage. According to the available evidence, the Consortium for Spinal Cord Medicine, Advanced Trauma Life Support, American Association of Neurological Surgeons, and Cervical
Spine Injury clinical practice guidelines all conclude that data are insufficient to definitely recommend the use of any neuroprotective agent including steroids. Because of SCI’s devastating consequences, there is ongoing research for novel therapies for patients with SCI. The research focus has been on both neuroprotective and neurogenerative therapies. The target of neuroprotective therapies is decreasing neuroinflammation, reducing free radicals (e.g., thyrotropin-releasing hormone, which showed some benefit in neurological recovery in a 20-patient study), reducing excitotoxic damage to the neurons (NMDA [N-methyl-d-aspartate] antagonist gacyclidine, which did not show a clinical benefit at 1 year post-SCI), improving blood flow (e.g., calcium channel blocker nimodipine, which failed to show benefit), and establishing homeostasis of neurohormones and ions.\textsuperscript{152-154}

Neuroprotective agents are aimed at promoting neuronal regeneration and restoration of axonal pathways to improve neurological function. GM1 ganglioside, a glycopeptide naturally found in high concentrations in the central nervous system (CNS), induces neuronal sprouting in vitro and promotes neuronal regeneration. Despite initial promising results, a recent Cochrane review found that GM1 was not beneficial.\textsuperscript{155}

Further therapies currently being investigated include rho antagonist, anti-Nogo antibodies, acidic fibroblast growth factor, autologous activated macrophages, and autologous mesenchymal stem cells.\textsuperscript{148}

**Blunt Injuries to the Thoracic Aorta**

**Causes and Classification**

Blunt injuries to the thoracic aorta are the second most common cause of death in trauma patients, with 80% dying before reaching a trauma center in the pre-airbag era. In the remaining patients who live to reach the hospital, 50% will die within 24 hours.\textsuperscript{156} Deaths in patients with injuries to the thoracic aorta are partly related to severe associated injuries if patients do not receive medication to decrease shear stress
on the area of injury. Arthurs et al. noted that 31% of patients with blunt aortic injuries had concomitant injuries to the brain, followed by abdominal (29%) and pelvic (15%) injuries.\(^{157}\) Blunt aortic injuries anatomically involve primarily the descending aorta (up to 65%), followed by an almost equal distribution among the ascending aorta, the distal descending aorta, and those with injuries at several sites.\(^{157}\) Mechanisms for aortic injury involve shear forces between the relatively mobile part of the vessel next to a fixed portion, compression of the vessel between bony structures, and profound intraluminal hypertension during the traumatic event.\(^{158}\) Blunt traumatic aortic injuries are different from classic aortic dissections because they are true local tears without intramural dissection. They can be separated into two categories: (1) traumatic true aneurysms, which are partial-thickness tears (intima and part of media of aorta) with blood staying in the lumen; and (2) traumatic false aneurysms, which are full-thickness tears (intima, media, adventitia) with blood outside the lumen (extravasation with free bleeding or into a collection).\(^{159}\) Blunt aortic injuries are typically diagnosed according to the mechanism of injury and CT angiography findings such as mediastinal hematoma, aortic pseudoaneurysm, variation in aortic contour, intimal flap, and thrombus.\(^{159}\) Blunt aortic injuries are graded in severity as follows: grade I injury involves intimal tear only, grade II involves intramural hematoma, grade III involves disruption contained within a pseudoaneurysm, and grade IV involves frank rupture.\(^{160}\)

**Management**

Surgical repair has long been the standard of care for managing blunt aortic injuries. One of the main challenges in the care of these trauma patients with blunt aortic injuries, as mentioned earlier, is the concomitant injuries that may delay immediate surgical intervention. As such, the Memphis group published two papers on the medical management of these patients with antihypertensive therapy (\(\beta\)-blockers plus vasodilators) until they are stable for surgical intervention, which set the foundation for the medical management of patients with
blunt traumatic aortic injuries. The first study evaluated 71 patients for 4 years with blunt aortic injuries, of whom 52 were managed surgically and 19 were managed medically. In the surgical group, seven patients died, with two of the deaths related to aneurysmal rupture. Among the medically managed group, although the mortality was higher because of concomitant injuries (9 of 19 [47%]), none of the patients died of aneurysmal rupture. The second paper evaluated 93 patients who were being assessed for suspected aortic injury. Most of the patients (67) were treated with early surgical repair followed by delayed repair with medical management in the interim (15) and no intervention being tried in 11; 8, 2, and 6 patients, respectively, died in each group. None of the patients in this study died of aortic rupture. Between these two papers, the goals for hemodynamic control involved a heart rate of less than 100 beats/minute and a systolic blood pressure of between 100 mm Hg and 110 mm Hg. These papers established the therapeutic standard with respect to the goals for the medical management of blunt aortic injuries using anti-hypertensive agents. Also of note is that β-blockade therapy was always initiated first with either intravenous esmolol or labetalol followed by vasodilator therapy with sodium nitroprusside. Current alternatives to sodium nitroprusside such as nicardipine and clevidipine are also used in treating these patients. More recently, a study by Rabin et al. showed that grade I and II injuries were amenable to medical management, whereas grade III and IV injuries benefited from surgical intervention, which helps further clarify the role for the medical management of these patients.

Historically, medical management of blunt aortic injuries was the cornerstone in patients with contraindications to immediate open surgical repair. In the past 2 decades, however, there has been a shift to endovascular repair. Although there are no randomized controlled studies directly comparing open surgical repair with endovascular repair, there has been an increasing trend toward using endovascular repair for these patients. In addition to the advances in and access to newer endovascular technologies, a growing body of literature shows improved outcomes with endovascular repair compared with
open surgical repair. Most recently, a meta-analysis from the Eastern Association for the Surgery of Trauma documented a statistically significant reduction in rates of mortality (8% vs. 19%, p=0.04) and paraplegia (0.5% vs. 3%, p=0.01) with no differences in stroke rates (9.1% vs. 6.7%, p=0.69) or renal failure rates (8.6% vs. 9.3%, p=0.70) in patients receiving endovascular repair versus open surgical repair. Of note, there was a fairly high rate of device-related complications (20%) in a 2008 study. However, with improvements in technology, more recent studies have shown only a 2.4% device complication rate during a 2.3-year period. With the growing safety and improved outcomes with endovascular repair, the need for temporary control with medical management has decreased in patients with multisystem trauma including blunt aortic injuries. One caveat to these data is that in patients with stable injuries, repair in a delayed fashion seems to have better outcomes than early repair, so medical management can be used in the interim in this subset of patients.

Traumatic Abdominal Injuries

Background
The concept of damage control laparotomy was first proposed by Stone et al. at Grady Memorial Hospital, where they showed that rapidly terminating the surgical procedure in patients with significant abdominal trauma and intraoperative metabolic failure resulted in improved outcomes. The term damage control, however, was not coined until almost a decade later by Rotondo et al. The adoption of damage control laparotomy as a surgical intervention to treat patients with blunt or penetrating abdominal trauma, in addition to advances in critical care medicine, has improved survival significantly. These patients, however, often have nutritional depletion, respiratory failure, renal failure, and, occasionally, the development of entero-atmospheric in an open abdomen. Although these complications present later in the ICU stay, they are still important issues for the critical care pharmacist to be aware of and manage.
Importance of nutritional support in the trauma patient stems from the 1970s, when multiorgan failure (now called multiorgan dysfunction syndrome [MODS]) evolved as a major clinical challenge in the critically ill trauma patient. It was recognized then that persistent catabolism with consumption of visceral protein stores and delayed immunosuppression were risk factors for MODS. Therefore, a focus of research ensued on the optimal nutritional support for the trauma patient. As our understanding of critically illness has evolved, we now recognize a condition termed persistent inflammation-immunosuppression catabolism syndrome (PICS), where the interplay between dysfunction of the immune system and protein catabolism may benefit from proper nutritional support as well. In the critically ill trauma patient, provision of nutrition through the appropriate route and at the appropriate dose is an important clinical consideration. Although the mechanisms for how the GI tract affects immune function are unclear, most clinical trials and a meta-analysis support enteral nutrition as the preferred route in trauma patients (Table 43.6). With this in mind, it is important to obtain access to the GI tract as soon as possible to optimize nutritional status, even if it is trophic feeds, based on the most recent publication. Although access to the GI tract can be challenging, there are a variety of nonsurgical methods for access. Jejunal feedings are optimal because of challenges with delayed gastric emptying, gastroesophageal reflux, and reduced lower esophageal sphincter tone (aspiration risk); however, feeding of the stomach in critically ill trauma patients has also been shown as a reasonable approach and may be easily initiated in the ICU with perioral or transgastric techniques. When enteral access is truly unobtainable or ill advised (GI discontinuity, open abdomen, persistent shock, etc.), it is reasonable to delay enteral nutrition (5–7 days) instead of initiating early total parenteral nutrition (TPN). In summary, early enteral nutrition is an important therapy in the treatment of trauma patients, and it is reasonable to initiate even in patients with significant abdominal trauma. In addition to reducing septic complications, enteral nutrition may play a role in modulating PICS, although that has yet to
be proven in clinical trials.

Complications

**Enterocutaneous Fistula—Diagnosis and Management**

With the increased use of damage control laparotomies and an associated temporary open abdomen, enterocutaneous fistula (ECF) and enteroatmospheric fistula have emerged as a rather challenging complication to manage. Enterocutaneous fistula is defined as an abnormal communication between the bowel and the skin and is associated with the triad of sepsis, fluid, and electrolyte abnormalities and malnutrition. Enterocutaneous fistula can be classified physiologically as low (less than 200 mL/day), moderate (200–500 mL/day), and high (greater than 500 mL/day) output. The incidence of ECF and enteroatmospheric fistulas in the trauma population ranges from 4.5% to 25% and is associated with significant morbidity and mortality. A recent paper by Bradley et al. identified resection of the large bowel, large-volume resuscitation, and multiple re-explorations as common risk factors for developing an ECF in the trauma population. Nutritional optimization is one key to managing ECF, and this is achieved through TPN, which also allows for minimized fistula output and improved wound care. Although some have advocated for the use of enteral nutrition distal to the fistula when feasible, no trials directly compare this with parenteral nutrition. Moreover, it is important to maintain appropriate fluid balance and electrolyte concentrations. Replacement of fluid losses from high-output fistulas should occur frequently (every 2–4 hours) to prevent dehydration and acute renal dysfunction. Hypokalemia is the most common electrolyte abnormality related to ECF, especially with those located in the upper GI tract. Therefore, incorporating potassium into the replacement fluid is mandatory. Duodenal or pancreatic fistulas tend to lose bicarbonate ions, so replacement with sodium bicarbonate is a reasonable intervention.

With respect to pharmacotherapy, the only drug that has been
evaluated in ECF is somatostatin and its analog octreotide. Somatostatin (and octreotide) has many effects on the GI tract, including enhanced fluid and electrolyte absorption and decreased secretion of gastric acid, pepsin, and bile.\textsuperscript{201,202} It suppresses smooth muscle contractility and therefore delays gastric emptying and small bowel motility.\textsuperscript{201,202} Because of its longer half-life, octreotide is used more often in the clinical setting.\textsuperscript{203} Regarding the role of octreotide in the management of ECF, several trials have been conducted through the years (Table 43.7). Overall, it appears that most of the trials show a reduction in time to closure, but not necessarily an increase in the percentage of patients who successfully close their fistulas. Because octreotide is a rather benign drug, it is not unreasonable to use this as an adjunct for the management of ECF for 2 weeks.

</table>
Another untoward complication of intra-abdominal trauma is short bowel syndrome (SBS).\textsuperscript{211,212} Short bowel syndrome is defined as a malabsorptive state after small bowel resection when the length of remnant small bowel is less than 200 cm.\textsuperscript{213} Short bowel syndrome in trauma is very rare, occurring in about 8% of trauma patients who were referred for the evaluation of SBS in one series. Injury to the intestinal blood supply was the most common reason (81%) for SBS, followed by direct injury (19%).\textsuperscript{214} The median length of small bowel in a human being is around 4 m and is divided into three sections: the duodenum (25–30 cm), the jejunum (160–200 cm), and the ileum (the rest).\textsuperscript{215,216} With respect to function, carbohydrate and protein metabolism occurs primarily in the duodenum and jejunum, bile salt and fat-soluble vitamin reabsorption occurs in the ileum, and fluid and electrolytes are absorbed in the ileum and colon. Therefore, SBS is caused by an extensive loss of the absorptive surface area of the small bowel.\textsuperscript{217,218} The ability of the small bowel to maintain an adequate nutritional status in the face of such massive re-section depends on the extent and location of the resection, presence of the ileocecal valve and colon, adaptation of the intestinal remnant, and nature and complications of underlying disease.\textsuperscript{214,219} Normal absorption of nutrients occurs within the first 100 cm of the jejunum; however, in patients for whom there is significant loss of the jejunum, the ileum is able to adapt by hyperplasia.\textsuperscript{220,221} The reverse, however, is not true, because specialized cells that manage vitamin B\textsubscript{12} and bile salt reabsorption cannot be replaced by jejunal hyperplasia.\textsuperscript{214} An additional complication in patients missing a significant portion of their ileum is large-volume diarrhea. If the colon is present, it may be able to adapt and significantly reduce water and electrolyte losses.\textsuperscript{222} Bacteria in the colon are also able to metabolize unabsorbed carbohydrates into short-chain fatty acids and lactate, which can be absorbed and provide additional calories.\textsuperscript{223}

In the patient with SBS, the treatment goals are to optimize
nutritional intake, whether it be enteral or intravenous, and manage fluid and electrolyte abnormalities as a result of profound diarrhea. Management of fluid and electrolyte losses will vary according to the sections of small bowel still available; therefore, a key understanding of the functional anatomy of the small bowel is important. Dehydration caused by water and sodium losses can be a result of significant resection of the jejunum (less than 100 cm remaining) in patients with a jejunostomy and should be managed aggressively with appropriate replacement of output with normal saline. Additional electrolyte abnormalities such as hypomagnesemia and hypocalcemia tend to be prevalent in the setting of resection of the jejunum as well, as the duodenum and proximal jejunum are absorption sites for these electrolytes. These losses are further exacerbated by their binding to unabsorbed long-chain fatty acids in patients who lack a terminal ileum because the terminal ileum is responsible for the re-absorption of bile salts and fat. The loss of calcium in the GI tract is also of concern because this facilitates the absorption of oxalate, which leads to the development of nephrolithiasis. Replacement of magnesium and calcium should be a key intervention in this group. Of note, calcium is administered orally at 800–1,200 mg daily in divided doses to replace losses and to bind to oxalate present in the GI tract to form insoluble calcium oxalate that is readily eliminated from the body. Replacement of fat-soluble vitamins (A, D, E) is important as well, with the exception of vitamin K because the colon synthesizes most of the supply. Therefore, patients with intact colons do not need replacement. The loss of the terminal ileum also results in the inability to absorb vitamin B₁₂, so supplementation is required in these patients.

The many approaches to managing diarrhea include the following: (1) reduce transit time through the GI tract, (2) decrease secretions by the GI tract, and (3) increase the absorptive capacity of the small bowel. Reductions in transit time can be accomplished by opioid or opioid-like agents such as loperamide, codeine, diphenoxylate/atropine, and tincture of opium. One study suggests that loperamide is more efficacious than codeine at reducing the output of an ileostomy;
however, the various therapies can be combined for additive effects. Octreotide has been evaluated for reducing the jejunal and ileal output or diarrhea in several small studies, and the overall results show a reduction in ostomy output, at least in the short term (Table 43.8). With respect to increasing absorptive capacity, the two therapeutic options are growth hormone (GH) and teduglutide. Growth hormone is a trophic factor that is thought to increase intestinal absorption. The data presented in Table 43.9 suggest that the overall GH used short term (4 weeks) increases overall intestinal absorption, reduces fecal weight or output, and increases patient weight. Of note, high-carbohydrate diets are necessary to see the benefits of GH therapy, together with concurrent supplementation of glutamine. Teduglutide is a novel GLP (glucagon-like peptide)-2 analog that appears to modulate the expansion of the intestinal mucosa by stimulating crypt cell growth and reducing enterocyte apoptosis. The data presented in Table 43.9 show significant reductions of TPN volume in patients who received teduglutide treatment for 24 weeks, and teduglutide has received U.S. Food and Drug Administration approval for the treatment of patients with SBS.

**Acute Kidney Injury**

**Background**

Acute kidney injury is a common complication in the trauma population, especially in patients experiencing significant blood loss and the resulting hypoperfusion. Less severe AKI has been reported at an incidence as high as 30% in the trauma patient. There is a higher in-hospital mortality risk in trauma patients developing AKI, especially in those requiring renal replacement therapy, than in their counterparts without AKI. This risk appears to increase with worsening degree of kidney injury. In a prospective observational trial, risk factors for developing AKI in the trauma patient included advanced age, higher ISS values (greater than 17), the presence of hemoperitoneum, shock, hypotension or bone
fractures, rhabdomyolysis with creatine phosphokinase greater than 10,000 IU/L, presence of respiratory failure requiring mechanical ventilation, and a GCS score less than 10.260

Pathophysiology of AKI in Trauma

In the trauma patient, renal function is affected by hypovolemia from hemorrhage, general anesthesia, intraoperative organ manipulation, postoperative fluid shifts, sepsis, rhabdomyolysis, and nephrotoxic agents. In hemorrhagic shock, the kidneys detect hypotension and respond by vasoconstriction of the efferent arterioles, which leads to an increase in renal vascular resistance with a concomitant decrease in renal blood flow.257 The result is a stable glomerular filtration rate, which permits the excretion of toxins and byproducts. Some blood flow (400 mL/minute) is directed to core areas. The phenomenon is termed auto-regulation and can be maintained with decreases in renal blood flow of up to 70% of the baseline.261 Further decreases in blood pressure lead to vasoconstriction of both afferent and efferent arterioles, resulting in decreased glomerular filtration rate. Once systolic blood pressure falls below 70 mm Hg, all blood is shunted away from the kidneys to the systemic circulation, and glomerular filtration ceases, leading to acute renal injury.257

Acute kidney injury not only occurs right after massive hemorrhage, but can also occur during surgery after the initial injury. In this case, anesthesia induction leads to hypotension, taking away the compensatory vasoconstriction of the kidneys to maintain glomerular filtration. Combined with hypovolemia secondary to ongoing bleeding, it can lead to acute renal failure and a decrease in urine output that persist even after the operating room.257 The main goal during surgery is to stabilize hemodynamics by expanding plasma volume with intravenous fluids and blood product transfusion.

After definitive bleeding management in the operating room, patients experience large fluid and electrolyte shifts during the extravascular fluid sequestration phase, which can again lead to decreased cardiac output, renal blood flow, glomerular filtration, and urine output.257 Diuresis with loop diuretics and the use of dopamine and
fenoldopam as renal vasculature dilators have both fallen out of favor, given evidence of no benefit and potential harm.\textsuperscript{262}

GH = growth hormone.
Other mechanisms of AKI include crush injuries accompanied by rhabdomyolysis, contrast-induced nephropathy, abdominal hypertension, and use of nephrotoxic medications.

**Types and Management**

Although trauma patients experience AKI because of various etiologies, only those specific to the trauma population will be covered in this section. To learn about other causes of AKI, please see other chapters in the book.

**Rhabdomyolysis-Associated AKI**

Rhabdomyolysis is a condition of muscle damage in which there is leakage of muscle cell contents including electrolytes, myoglobin, and other proteins such as creatine phosphokinase into the circulation.\(^{263}\) The clinical presentation of rhabdomyolysis includes limb weakness, myalgia, swelling, and gross pigmenturia without hematuria.\(^ {263}\) Rhabdomyolysis can be seen in the trauma patient secondary to a direct muscle injury (e.g., blunt trauma or burns) or hypoxic muscle injury (e.g., penetrating trauma, peripheral vascular disease) and accounts for up to 28% of cases of posttraumatic AKI requiring dialysis.\(^ {264}\) AKI is caused by intrarenal vasoconstriction, direct and ischemic injury to the tubules, and renal tubular obstruction by myoglobin.\(^ {263}\)

Renal vasoconstriction occurs as a result of intravascular fluid depletion secondary to fluid sequestration within the damaged muscle, decreased concentrations of the vasodilator nitric oxide, and increased mediators of vasoconstriction such as endothelin-1 and tumor necrosis factor α.\(^ {263}\) In addition, myoglobin is a heme protein containing ferrous oxide (Fe\(^{2+}\)). When it binds to oxygen, it forms ferric oxide (Fe\(^{3+}\)), a hydroxyl radical that causes injury to renal cells. A creatine phosphokinase concentration greater than 5,000 U/L, a serum creatinine concentration greater than 1.5 mg/dL, a base deficit of -4 or less, and myoglobinuria are predictive of AKI after an episode of rhabdomyolysis.
Management of rhabdomyolysis includes repleting intravascular volume through early, aggressive fluid resuscitation; administering intravenous fluids at 400 mL/hour; and producing a urine output of 3 mL/kg/hour until creatine phosphokinase concentrations are decreased.\textsuperscript{265,266} Alkalinization of the urine has the theoretical benefits of decreasing the precipitation of protein-myoglobin complex, inhibiting redox cycling of myoglobin and reducing injury to the tubules, and decreasing vasoconstriction caused by metmyoglobin in the acidic urine.\textsuperscript{266} Clinical evidence on the use of sodium bicarbonate has not firmly confirmed its theoretical benefits, but it is important to recognize that hyperchloremic metabolic acidosis can result with the administration of large volumes of 0.9% sodium chloride.\textsuperscript{267} In patients who may be at risk of developing hyperchloremic metabolic acidosis, use of sodium bicarbonate may be a reasonable alternative.\textsuperscript{263} The use of diuretic in rhabdomyolysis remains controversial. Mannitol, an osmotic diuretic, increases urinary flow by creating a fluid concentration gradient from the injured muscle into the vasculature as well as acting as a free-radical scavenger, but its use has yet to be validated, and higher doses of mannitol can cause renal vasoconstriction and tubular toxicity, leading to renal failure (osmotic nephrosis).\textsuperscript{268,269} Diuretics should not be used in patients with hypovolemia.

Renal replacement therapy is indicated in the patient with rhabdomyolysis in whom there are indications for dialysis such as acidosis or volume overload.\textsuperscript{270}

**Increased Intraperitoneal Pressure–Associated AKI**

Trauma patients with massive hemorrhage or late septic shock requiring large-volume resuscitation may develop abdominal compartment syndrome. The increased pressure leads to a reduction in renal blood flow and glomerular filtration rate. Once abdominal decompression has been achieved through celiotomy, renal blood flow is restored, provided interruption was not prolonged and intrinsic renal injury has not taken place.\textsuperscript{263}
Extremities: Deep Venous Thrombosis Prophylaxis in Trauma

Epidemiology and Risk Factors

Venous thromboembolism (VTE) is unfortunately a common and potentially life-threatening complication of trauma. The incidence of VTE within the trauma population ranges from 5% to 63% depending on risk factors, mode of detection, and type of prophylaxis; however, a meta-analysis reported a pooled rate of 11.8% for deep venous thrombosis (DVT) and 1.5% for pulmonary embolism. The trauma population is at a particularly higher risk than the general population for VTE because it tends to possess most, if not all, of Virchow triad, specifically coagulopathy, vascular injury, and immobility. Vascular injury and immobility are obvious risk factors in the trauma population. The causes of DVT require a deeper understanding of the pathophysiologic changes related to traumatic injury. The data suggest that several changes in the clotting cascade occur, specifically decreases in antithrombin III, decreases in proteins C and S, suppression of fibrinolysis, increases in tissue factor release, and increases in thrombin generation. A multivariate analysis in the prospective study by Geerts et al. established that the major clinical risk factors for VTE in trauma were age, blood transfusions, surgery, fractures of the femur or tibia, and injury to the spinal cord. In addition, a study by Knudson et al. highlighted that patients with traumatic injuries who were immobile for more than 3 days or who had either pelvic or lower extremity fractures were also at high risk of VTE.

Prevention

With trauma patients carrying several risk factors, pharmacologic prophylaxis for VTE prophylaxis is imperative. Table 43.10 summarizes these data. Of note, both studies by Knudson et al. had low DVT rates and were therefore underpowered to find a difference. The landmark study that established enoxaparin as the drug of choice for
DVT prophylaxis in the trauma population was conducted by Geerts et al. and compared heparin 5,000 units with enoxaparin 30 mg given subcutaneously twice daily. Some have challenged the use of venography in this study as an oversensitive detector of clinically asymptomatic VTEs; however, venography was the gold standard at the time of this study. With respect to the significance of asymptomatic VTEs, practice dictates their detection, and the risk of pulmonary embolisms warrants management. Despite the lack of randomized controlled trials evaluating low-molecular-weight heparins in patients with trauma since the Geerts et al. study, the strength of recommendation for low-molecular-weight heparin fell from a 1A recommendation to a 2C in the most recent iteration of the CHEST guidelines. The reason for this change is based on the redefining of a “significant event” from including any type of VTE to including only fatal pulmonary embolism, nonfatal pulmonary embolism, and symptomatic DVT or VTE. Nonetheless, low-molecular-weight heparins continue to play a pivotal role in preventing VTE in trauma patients. Figure 43.1 is a suggested algorithm for evaluating a trauma patient for VTE prophylaxis given the data discussed in this chapter.

DVT = deep venous thrombosis; SCD = sequential compression device.
In addition to selecting the optimal agent, the time to initiate DVT prophylaxis in the critically ill trauma patient can be challenging. Injuries in which the consequences of bleeding are high include TBI, injuries to solid organ (liver, spleen, kidney), and injuries to the spinal cord, and the clinician may be hesitant to initiate early prophylactic therapy. Nathens et al. performed a retrospective analysis of concurrently collected data on 315 trauma patients who were divided into three groups as follows: patients with DVT prophylaxis initiated within 48 hours, patients who received no DVT prophylaxis, and patients who received DVT prophylaxis after at least 7 days of injury. The data showed a 3-fold increased risk of DVT when therapy was delayed beyond 4 days (risk ratio -3; 95% CI, 1.4–6.5). A second study by Aito et al. of 275 patients with injury to the spinal cord also showed a trend toward fewer DVTs in patients who received DVT prophylaxis within 3 days than in those who received DVT prophylaxis 8–28 days later (2% vs. 26%). A more recent prospective study by Stannard et al. of 224 patients showed that those who had early mechanical prophylaxis followed by delayed pharmacologic prophylaxis had DVT rates similar to those who had early pharmacologic prophylaxis. This study, however, excluded patients with severe TBI and SCIs who are known to be at high risk. Two studies have evaluated the safety of early pharmacologic prophylaxis in high-risk DVT populations. Alejandro et al. evaluated bleeding risks in a retrospective analysis of 188 trauma patients who received low-molecular-weight heparin after blunt splenic injuries. Patients who were initiated on DVT prophylaxis early (less than 48 hours) had similar nonoperative management failures (4% vs. 6%, p=0.593) and transfusion requirements (50 vs. 56.2%, p=0.507). A retrospective analysis by Eberle et al. of 312 trauma patients with blunt abdominal organ injuries who were treated nonoperatively showed that the patients who were initiated on DVT prophylaxis within 48 hours of injury had rates of failure of nonoperative management and bleeding rates similar to those who were initiated early. Although the early initiation group had a lower ISS, they had risk factors for bleeding similar to those of the group with late initiation of prophylaxis. A
A prospective observational study by Norwood et al. of 525 patients with TBI (mean GCS score of 10 – moderate TBI) who were initiated on DVT prophylaxis with enoxaparin within 48 hours of injury showed that 3.4% (n=18) of patients developed progressive hemorrhage after the initiation of enoxaparin, although most (n=12) had no change in neurological status or outcome. Of note, 10 of the 18 patients with further hemorrhage had protocol violations in which enoxaparin was initiated before the repeat CT of the brain at 24 hours (75 protocol violations for the entire study). If these were excluded, this would have reduced the rate further to 1.8%. Because of these findings, the authors concluded that early enoxaparin is a reasonable intervention in the population with TBI, although only after a stable repeat head CT at 24 hours. Because of the limited data, neither the Brain Trauma Foundation guidelines nor the Eastern Association for the Surgery of Trauma guidelines for the nonoperative management of blunt splenic or hepatic injury make a recommendation for the timing of VTE prophylaxis at this time.

![Flowchart Image]

**Patient presents with traumatic injury**

Does patient have contraindication to pharmacologic prophylaxis (solid organ injury, TBI, high-risk surgery)?

- **Initiate mechanical prophylaxis**
- **High risk of VTE (ISS > 9, long bone or pelvic fractures, spinal cord injury)**
  - **Initiate low-molecular-weight heparin (± mechanical prophylaxis)**
  - **Initiate low-dose unfractionated heparin**
Although the CHEST guidelines recommend the use of mechanical prophylaxis in addition to pharmacologic prophylaxis, there are very poor data to support this practice. ISS = injury severity score; VTE = venous thromboembolism.

The final challenge with VTE prophylaxis is dosing. Although no clinical outcome data are currently associated with the dosing of VTE prophylaxis, an astute clinician should consider the following. In a pharmacokinetic study of trauma patients, Haas et al. showed that the antifactor Xa activity of 30 mg of subcutaneous enoxaparin is highly variable and drops below the therapeutic range of 0.1–0.2 IU/mL, especially in patients with profound edema (greater than 10 kg). A pharmacokinetic study by Rutherford et al. that evaluated a subcutaneous injection of 40 mg once daily in trauma patients also showed that, although mean peak activity was therapeutic, mean trough concentrations were well below the therapeutic target range (mean 0.044 IU/mL). The authors recommended against this regimen for routine prophylaxis in the trauma population. Most recently, a paper by Costantini et al. recommended a protocol for adjusting the enoxaparin dose to achieve therapeutic peak concentrations of 0.2–0.4 IU/mL and showed no increased bleeding with the higher doses (range 40–60 mg twice daily). In summary, these papers highlight the pharmacokinetic derangements that occur in the critically ill trauma patient. Further study is warranted to assess whether an adjustment in the dose of enoxaparin reduces VTE rates without worsening the bleeding risk.

In conclusion, drug therapy plays a critical role in managing the various conditions that patients with traumatic injuries may experience. Knowledge of the complex interaction between the pathophysiologic changes that occur in trauma and drug therapy is essential for the pharmacist to provide optimal clinical care to these patients. This chapter is not all-inclusive because it pertains to drug therapy in
trauma, but it is a primer for the major pharmacotherapy needs of this population and will assist the clinician in providing that optimal care.

LEARNING OBJECTIVES

1. Identify the most common cause of cardiac arrest in pediatric patients.

2. Know the different types of shock and those that occur most commonly in children.

3. Describe the initial treatment of all forms of pediatric shock, and understand why the treatment of shock in pediatric patients may differ from that in adults.

4. Understand why the incidence of septic shock is highest in the first year of life and the impact of underlying medical conditions on mortality rate.

5. Explain why the definitions of systemic inflammatory response syndrome are different between pediatric and adult patients.

6. Describe how the normal physiology of children causes them to respond to septic shock differently from adults.

7. Understand that developmental changes and immaturity of the respiratory system make respiratory distress the most common reason for hospital admission in the first year of life.

8. Develop a pharmacotherapy plan for a pediatric patient with status asthmaticus admitted to the PICU.

9. Describe why the different choices for the pharmacotherapy of intubation vary depending on the cardiovascular stability of the patient, the stomach being empty or full, and the underlying cause of the respiratory distress.
10. Understand how the anatomic differences of the child’s brain render it more susceptible to certain types of injuries after head trauma.

11. Develop a pharmacotherapy plan for the treatment of traumatic brain injury in a pediatric patient, understanding that goals may differ according to the patient’s age.

12. Understand why stress ulcer prophylaxis, a standard of care in the adult ICU, is less well defined in the PICU.

13. Explain differences in the risk of developing deep venous thrombosis (DVT) depending on age and possible sources of DVT in critically ill children.

14. Explain why infants are at a higher risk of hypoglycemia than are older children, discuss the importance of point-of-care glucose testing, and develop a pharmacotherapy plan for the treatment of hypoglycemia, if identified.

ABBREVIATIONS IN THIS CHAPTER

GCS Glasgow Coma Scale
INTRODUCTION

The epidemiology of patients admitted to either the pediatric emergency department (ED) or the pediatric intensive care unit (PICU) differs from that typically seen in adult critical care settings. In an evaluation of 361 children presenting to an ED, the most common medical reasons for admission were cardiocirculatory causes (32%), neurological conditions (26%), and respiratory causes (23%). Cardiocirculatory causes included hypovolemic, septic, cardiac, and anaphylactic shock. Neurological conditions consisted primarily of seizures, status epilepticus, and meningitis or encephalitis. The most common respiratory cause for admission was respiratory syncytial virus (RSV) bronchiolitis, followed by pneumonia, pleural effusions, and status asthmaticus (SA). Eighteen percent of the patients were admitted after trauma. Diabetic ketoacidosis accounted for 6% of the admissions. Other diagnoses included intoxications, near-drowning, snakebites, and burns. An assessment of the most common causes for
PICU admission showed similar results. In a review of 1,149 children admitted during a 2-year period to the PICU of a university-affiliated children’s hospital, most (38%) were given a diagnosis of cardiovascular diseases, followed by respiratory illnesses (28%), other medical causes (10%), neurologic illness (8%), and trauma (8%). Another 7% were admitted for postoperative care. In the past 10 years, fewer children have been admitted to the PICU after accidents or with croup or epiglottitis. These changes can be explained by the requirement for mandatory car seats for children, administration of dexamethasone in the ED to patients with croup, and universal administration of the conjugate Haemophilus influenzae type b immunization.

Much of pediatric practice is dedicated to helping the child make the transition from the intrauterine environment through infancy, childhood, and adolescence to adulthood. One of the greatest challenges in treating pediatric patients is recognizing the many developmental physiologic changes and understanding how they affect assessment and treatment of the patient. These differences are discussed in detail as they pertain to specific disease states and summarized in Table 44.1. The definition and presentation of many disease states encountered in the critical care setting, including respiratory depression, supraventricular tachycardia, hypotension, and shock, vary depending on the age of the patient because of physiologic variations. There are also newborn emergencies that are unique to the physiologic transitions that occur in the first month of life. Pediatric health care providers practicing in critical care settings such as the ED or the PICU must be adept at incorporating these physiologic differences into medication selection, dosing, and monitoring to optimize patient care.

**Pediatric Cardiopulmonary Resuscitation**

In marked contrast to studies of pediatric cardiac arrest, adult cardiac arrest studies have focused on the diagnosis and treatment of ventricular fibrillation (VF) in both inpatient and out-of-hospital cardiac arrest. Studies have shown that VF is the most common initial
dysrhythmia in adults with sudden death; in some reports, the prevalence of VF was 60%–85%. Cardiac arrest caused by VF or pulseless ventricular tachycardia as the initial cardiac rhythm occurs in only 5%–15% of pediatric cases of in-hospital and out-of-hospital cardiac arrest. In contrast to adults, cardiac arrest in infants and children does not usually result from a primary cardiac cause; more often, it is the terminal result of progressive respiratory failure or shock. Therefore, it is essential to recognize and aggressively treat pediatric patients admitted with respiratory distress, pneumonia, and shock to prevent the development of systemic hypoxemia, hypercapnia, and acidosis, which may then progress to bradycardia, hypotension, and eventually cardiorespiratory arrest.

The adult advanced cardiovascular life support guidelines recommend 40 units of vasopressin or epinephrine as the first or second dose of medication administered to adults with asystole, with subsequent medication doses as epinephrine. Epinephrine is the drug of choice for managing pediatric asystole. Subsequent doses of epinephrine can be administered every 3–5 minutes by the intravenous or intraosseous route, using the appropriate intravenous/intraosseous dose of 0.01 mg/kg using the 1:10,000 or 0.1-mg/mL concentration (maximum 0.1 mg/dose). Treatment of pediatric asystole does not include vasopressin administration because progressive respiratory failure and shock, not underlying cardiovascular disease, are the most common causes of asystole in pediatric patients.

**Shock**

Shock may be classified as hypovolemic, distributive, cardiogenic, or obstructive. Hypovolemic shock is the most common type of shock in pediatric patients, typically caused by acute gastroenteritis. Hypovolemic shock occurs when circulating intravascular volume decreases to a point at which adequate tissue perfusion can no longer be maintained. Hypovolemia causes a decrease in preload and adversely affects cardiac output (CO). Initially, hypovolemia activates the peripheral and central baroreceptors that cause catecholamine-
mediated vasoconstriction and tachycardia. This initial response can maintain adequate circulation and blood pressure even after an acute loss of as much as 15% of the circulating blood volume. Shock is caused by inadequate blood flow and oxygen delivery to meet the metabolic demands of the tissues and progresses from an initial compensated state to a decompensated shock. Typical signs of compensated shock include tachycardia, cool and pale distal extremities, prolonged (greater than 2 seconds) capillary refill, weak peripheral pulses compared with central pulses, and normal systolic blood pressure. As shock progresses, patients exhaust their ability to compensate. These patients will have signs of inadequate end organ perfusion, including depressed mental status and decreased urine output.

and elastic tissue are not developed until school age and may easily become obstructed as a result of laryngospasm, bronchospasm, and edema or mucus accumulation

The cartilaginous ribs of the infant and young child are twice as compliant as the bony ribs of the older child or adult. During episodes of respiratory distress, the infant’s chest wall will retract further than will that of a patient with a bony rib cage

This will reduce the patient’s ability to maintain functional residual capacity (FRC) or increase tidal volume, thus further increasing the patient’s work of breathing

The alveolar epithelium and endothelial layers continue to develop until 10–12 yr of life

Discrete lung injury early in life may not impair lung development because compensatory alveolar growth may occur

The intercostal muscles are not fully developed until school age, so they act primarily to stabilize the chest wall during the first years of life. Because the intercostal muscles have neither the leverage nor the strength to lift the rib cage in the young child, the diaphragm is responsible for the generation of tidal volume

Anything that impedes diaphragm movement, such as a large stomach bubble, abdominal distension, or peritonitis, can result in respiratory failure in the young child

The narrowest part of the pediatric airway is the cricoid cartilage, not the vocal cords

Treatment of postextubation stridor may be more difficult. Therefore, use of dexamethasone 0.25–0.5 mg/kg/dose (max 10 mg/dose) IV q 6 hr for four to eight doses has been used as preventive therapy in traumatic intubations or in patients with no leak pressure
| Neurologic | 1. Infants and young children have large, heavy heads. The head is unstable because of its relative size to the rest of the body |
| | 2. The infant's weak neck muscles also allow for greater movement when the head is acted on by acceleration/deceleration forces |
| | 3. The skull is thinner during infancy and early childhood, providing less protection for the brain and allowing forces to transfer more effectively across the shallow subarachnoid space |
| | 4. The base of the infant's skull is relatively flat, which also contributes to greater brain movement in response to acceleration/deceleration forces |
| | 5. The infant's brain has a higher water content (~88% vs. 77% in an adult), which makes the brain softer and more prone to acceleration/deceleration injury. The infant brain is typically fully myelinated by 1 yr of age |

<p>| 1. If an infant or young child falls a significant distance, is ejected during an MVC, or is thrown from a bicycle after colliding with an automobile, the head will tend to lead (i.e., the infant or child will fly head first), and severe head injuries will occur when the head ultimately strikes the ground or another object |
| 2. Infants are at higher risk of acceleration/deceleration injuries |
| 3. The brain water content is inversely related to the myelination process, and the higher percentage of unmyelinated brain in neonates and infants makes them more susceptible to sheer injuries |
| 4. There are differences in the pathology after pediatric TBI by age group. In infants and young children, diffuse injury, such as diffuse cerebral swelling, and subdural hematomas are more common than focal injury, such as contusions, which are typically seen in older children and adults. The typical pattern of hypoxic-ischemic injury in infants and young children after NAT is rarely seen in older children and adults |</p>
<table>

<td>Development of GFR is linear as long as the neonate is born &gt; 34 weeks’ gestation. Children reach an adult GFR at ~12–19 mo. The Schwartz equation should be used to calculate creatinine clearance in children</td>
<td>In the first years of life, cannot use the absolute number calculated from the Schwartz equation to decide whether medication doses need to be adjusted, but must adjust when they drop below 50% of normal. At 1 yr, you may use the calculated number. Cannot use a Cockcroft-Gault equation to calculate creatinine clearance in infants, children, or adolescents. It will overestimate their clearance</td>
</tr>
<tr>
<td>Immune system</td>
<td>Passive immunity is normally conveyed from the mother to the fetus through transmission of immunoglobulins during the last trimester. As a result, premature neonates are immunoglobulin-deficient. Even the full-term neonate has decreased polymorphonuclear leukocyte function and small polymorphonuclear storage pools compared with older children and adults, as well as decreased ability</td>
<td>Infants and children &lt; 7 yr are particularly vulnerable to polysaccharide-carrying bacteria. Historically, Haemophilus influenzae, Streptococcus pneumoniae, and Neisseria meningitidis caused most of the</td>
</tr>
</tbody>
</table>
to synthesize new antibodies. Finally, neonates cannot make and deliver adequate amounts of phagocytes to infection sites. Stores of maternal immunoglobulin are depleted at 2–5 mo of age. Adult levels of immunoglobulin are not typically achieved until 4–7 yr of age. Low immunoglobulin levels also make the infant susceptible to viral infections.

1. Neonates and infants < 3 mo with temperature ≥ 38°C should be evaluated with blood, urine, and possibly CSF cultures.

2. Nosocomial infections in infants and children < 7 yr tend to be bacteremias and pneumonias (not UTIs and wound infections); therefore, empiric antibiotics until cultures are negative are appropriate.

BP = blood pressure; GFR = glomerular filtration rate; HR = heart rate; IV = intravenous(ly); MVC = motor vehicle collision; NAT = nonaccidental trauma; q = every; SVT = supraventricular tachycardia; TBI = traumatic brain injury; UOP = urinary output; UTI = urinary tract infection.

Initial volume resuscitation in all forms of shock is similar. It is recommended to push isotonic crystalloid fluid (i.e., normal saline or lactated Ringer solution) in 20-mL/kg boluses administered over 5 minutes. Immediately afterward, the patient should be assessed for signs of improved perfusion using clinical criteria such as reduction in heart rate, improvement in blood pressure, capillary refill, quality of pulses, and change in mental status. If the clinical signs of shock persist, another 20 mL/kg of isotonic fluid should be administered, reaching, if necessary, at least 60 mL/kg within the first 15–30 minutes of treatment.4,5

This aggressive resuscitation strategy was recently questioned after publication of the Fluid Expansion as Supportive Therapy (FEAST)
study evaluating the efficacy of fluid boluses in African children with severe infection. This study enrolled about 3,150 patients from age 60 days to 12 years who presented with a severe febrile illness complicated by impaired consciousness, respiratory distress, or both and evidence of impaired perfusion. Patients were randomized to 20–40 mL/kg of albumin 5% or 0.9% saline solution versus no fluid bolus (control). The 48-hour mortality was 10.6% (albumin), 10.5% (saline), and 7.3% (control). The reported relative risk of death between groups was as follows: saline bolus versus control 1.44 (confidence interval [CI], 1.09–1.9; p=0.01), albumin bolus versus saline bolus 1.01 (CI, 0.78–1.29; p=0.96), and any bolus versus control 1.45 (CI, 1.13–1.86; p=0.003). It is unclear whether these data can be extrapolated to all patient groups. Fifty-seven percent of the patients enrolled had a diagnosis of malaria. Around 45% of the patients enrolled received a blood transfusion. These percentages are much higher than those reported in U.S. and European studies evaluating the choice of fluids for resuscitation in pediatric patients with severe infection and shock. Further studies will be required before a change is made in the current recommendations.  

The therapeutic end points of fluid resuscitation in patients with shock are capillary refill less than 2 seconds, normal pulses with no difference between central and peripheral pulses, warm limbs, urine output greater than 1 mL/kg/hour, normal mental status, decreased lactate as measured on arterial blood gases (ABGs), and increased base deficit. Children normally have a lower blood pressure than do adults and can better preserve adequate blood pressure by vasoconstriction and increasing heart rate. As a result, blood pressure by itself is not a reliable end point for evaluating the adequacy of resuscitation in children. Hypotension is the last thing to occur in pediatric shock states. The definition of hypotension, stated as the 5% for systolic blood pressure for age in the 2015 pediatric advanced life support guidelines, is as follows:

- less than 60 mm Hg in term neonates (0–28 days)
- less than 70 mm Hg in infants (1–12 months)
- less than 70 mm Hg + (2 × age in years) in children 1–10
years of age
- less than 90 mm Hg in children 10 years or older

Fluid resuscitation should be continued until there is clinical improvement or an apparent hypervolemic state, as evidenced by rales, a gallop rhythm, or hepatomegaly.

**Septic Shock**

In 1969, an analysis of gram-negative sepsis showed a 98% mortality rate in children when shock syndrome developed. In a recent population-based study of U.S. children with severe sepsis (defined as bacterial or fungal infection with at least one acute organ dysfunction), Hartman et al. reported an increase in the incidence of severe sepsis in 2000–2005 as 0.56–0.89 cases, respectively, per 1,000 children. In addition, the increase reported in newborns was from 4.5 to 9.7 cases per 1,000, led by sepsis in very low birth weight neonates. In children 15–19 years of age, the reported increase was from 0.37 to 0.48 cases per 1,000. The mortality rate in this study was 8.9%, unchanged from in 2000, but significantly lower than that reported for adult patients with severe sepsis and septic shock (about 30% and 50%, respectively). This dramatic improvement in outcome has been achieved through a better understanding of the physiology of shock. The use of aggressive fluid resuscitation and the implementation of time-sensitive goal-directed therapies, as well as the application of technologic advances in respiratory, cardiovascular, renal, and nutritional support and the improvement in antibacterial, antiviral, and antifungal therapy, have resulted in improved survival in infants and children with septic shock and the resultant multisystem organ failure. Watson and colleagues found that 49% of sepsis cases occurred in children who had underlying illnesses that might place them at risk of higher morbidity and mortality. In the Children’s Hospital of Pittsburgh, the mortality rate from sepsis for children who were previously healthy was 2% compared with 12% in children with chronic illnesses.
PHYSIOLOGIC DIFFERENCES

Infants and young children are at a higher risk of severe systemic illness after infection than are adults. Infants are particularly vulnerable to infections for several reasons. Passive immunity is normally conveyed from the mother to the fetus through the transmission of immunoglobulins during the last trimester. As a result, premature neonates are immunoglobulin-deficient. Even the full-term neonate has decreased polymorphonuclear leukocyte function and small polymorphonuclear storage pools compared with older children and adults, as well as decreased ability to synthesize new antibodies. Finally, neonates cannot make and deliver adequate amounts of phagocytes to infection sites. This leaves them particularly vulnerable to polysaccharide-carrying bacteria and explains why, historically, H. influenzae, Streptococcus pneumoniae, and Neisseria meningitidis have caused most of the significant infections in the first years of life. Low immunoglobulin levels also make the infant susceptible to viral infections. Stores of maternal immunoglobulin are depleted at about 2–5 months of age. Adult immunoglobulin levels are not typically achieved until 4–7 years of age. Because of these physiologic differences, as well as differences in bacterial resistance patterns, the list of most likely pathogens in children with sepsis differs from that in adults. Table 44.2 lists common pediatric pathogens and appropriate empiric antibiotic coverage. Antibiotics should be administered within 1 hour of diagnosis, after the collection of appropriate cultures.

In an effort to develop a consensus definition of the pediatric sepsis continuum including systemic inflammatory response syndrome (SIRS), infection, sepsis, severe sepsis, septic shock, and multisystem organ dysfunction syndrome, a group of international experts in the fields of adult and pediatric sepsis and clinical research gathered in 2002. A panel was chosen that consisted of published pediatric critical care physicians and scientists with clinical research experience in pediatric sepsis.16

Because the clinical variables used to define SIRS and organ dysfunction are greatly affected by the normal physiologic changes that occur as children age, the group first defined six age-specific clinical and physiologic categories for vital sign and laboratory variables to meet SIRS criteria (Table 44.3): newborn, neonate, infant, toddler and preschool, school-aged child, and adolescent and young adult. Premature infants were not included because their care occurs primarily in NICUs (neonatal intensive care units), not PICUs.

SIRS = systemic inflammatory response syndrome.
Before discussing treatment, practitioners should understand the terms used to define sepsis. In 1992, SIRS was proposed by the American College of Chest Physicians and the Society of Critical Care Medicine to describe the nonspecific inflammatory process occurring in adults after trauma, infection, burns, pancreatitis, and other diseases.\textsuperscript{16,17} Sepsis was defined as SIRS associated with infection.\textsuperscript{17,18} The SIRS criteria were developed for use in adults. Not until 2005 was a consensus definition published for SIRS in children; this definition is listed in Table 44.4. A separate pediatric definition for SIRS was essential. Tachycardia and tachypnea, pivotal to the adult definition of SIRS, are common presenting symptoms of many pediatric disease processes. Therefore, the pediatric definition also includes that temperature and leukocyte abnormalities be present. Finally, numeric values for each criterion were established to account for the different physiology in children. Table 44.5 gives the age-specific cutoffs for each criterion. These values were established according to the expert

opinion of the international panel on sepsis that was convened in 2002.

Temperature is one of the features of the pediatric SIRS definition. A core temperature of greater than 38.5°C or less than 36°C may indicate serious infection. A core temperature is one measured by rectal, bladder, oral, or central catheter probe. Hypothermia is more likely to occur in infants. Temperatures measured by the tympanic, toe, or auxiliary route are not sufficiently accurate. Temperature may also be documented by a reliable source at home within 4 hours of presentation to the hospital or physician’s office. If environmental overheating, such as that produced by over-bundling, is suspected, the child should be returned to a neutral temperature environment, unbundled, and the temperature measurement repeated in 15–30 minutes.

In children, SIRS requires the presence of an abnormal temperature (hypothermia or hyperthermia) or an abnormal leukocyte count (low or high) in the presence of tachypnea and tachycardia. Sepsis is defined as the proven or suspected infection in the setting of SIRS. Severe sepsis is defined as sepsis in the setting of acute respiratory distress syndrome, cardiovascular organ dysfunction, or two or more acute organ dysfunctions (respiratory, renal, hematologic, neurologic, or hepatic). Organ dysfunctions are modified for children and summarized in Table 44.6. Carcillo et al. defined septic shock in pediatric patients as the presence of tachycardia and poor perfusion, including decreased peripheral pulses compared with central pulses, altered alertness, capillary refill greater than 2 seconds, mottled or cool extremities, and decreased urine output. The definition of septic shock in children does not include hypotension, as required in adults. This is because children often maintain their blood pressure until they are severely ill. Shock may occur long before hypotension occurs in children with septic shock (failure to improve with adequate fluid resuscitation), catecholamine-resistant septic shock (failure to improve with fluids and catecholamines), and refractory septic shock (failure to improve with fluids, catecholamines, and vasodilators). In addition, there are developmental differences in the hemodynamic response to sepsis between neonates, children, and adults. Practitioners in the
PICU may encounter all age ranges and must thus be familiar with the clinical differences between age groups because this may affect therapy.

Adult and pediatric patients have different adaptive responses that must be considered when selecting therapeutic management. This is important for pediatric practitioners to understand because many adolescent patients may respond as an adult. Among adult patients, the most common hemodynamic alterations include diminished systemic vascular resistance (SVR) and elevated CO. Systemic vascular resistance is diminished because of decreased vascular responsiveness to catecholamines, alterations in α-adrenergic receptor signal transduction, and the elaboration of inducible nitric oxide synthase. Adults have myocardial dysfunction with a decreased ejection fraction; however, CO is maintained or increased by tachycardia and reduced SVR.

Pediatric septic shock is associated with severe hypovolemia, and children often respond well to aggressive fluid resuscitation. Pediatric patients have diverse hemodynamic profiles during fluid-refractory septic shock: 58% have low cardiac indexes responsive to inotropic medications with or without vasodilators, 20% have high cardiac indexes and low SVR responsive to vasopressor therapy, and 22% present with both vascular and cardiac dysfunctions, necessitating the use of vasopressors and inotropic support. The pediatric patient is different from the adult patient with septic shock because low CO, not low SVR, is associated with mortality in pediatric septic shock. In fact, 78% of children show some degree of cardiac dysfunction on presentation after fluid resuscitation. Furthermore, about 50% of patients require a change in their vasopressor or inotropic management, or the addition of another agent, emphasizing that the hemodynamic status in children can change rapidly. Finally, a reduction in oxygen delivery rather than a defect in oxygen extraction can be the major determinant of oxygen consumption in children.

Table 44.6 Organ Dysfunction Criteria
Cardiovascular Dysfunction

Despite administration of isotonic IV fluid bolus ≥ 40 mL/kg in 1 hr

• Decrease in BP (hypotension) < 5th percentile for age or systolic BP < 2 SD below normal for age\(^a\) OR

• Need for vasoactive drug to maintain BP in normal range (dopamine > 5 mcg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose) OR

• Two of the following:
  • Unexplained metabolic acidosis: Base deficit > 5 mEq/L
  • Increased arterial lactate > 2 times the upper limit of normal
  • Oliguria: Urine output < 0.5 mL/kg/hr
  • Prolonged capillary refill: > 5 s
  • Core to peripheral temperature gap > 3°C

Respiratory\(^b\)

• Pao\(_2\)/Fio\(_2\) < 300 in absence of cyanotic heart disease or preexisting lung disease OR

• Paco\(_2\) > 65 torr or 20 mm Hg over baseline Paco\(_2\) OR

• Proven need\(^c\) or > 50% Fio\(_2\) to maintain saturations > 92% OR

Need for nonelective invasive or noninvasive mechanical ventilation\(^d\)

Neurologic

• GCS < 11 OR

• Acute change in mental status with a decrease in GCS ≥ 3 points from abnormal baseline

Hematologic

• Platelet count < 80,000/mm\(^3\) or a decline of 50% in platelet count from highest value recorded during the past 3 days (for chronic hematology/oncology patients) OR

• International normalized ratio > 2

Renal

• Serum creatinine > 2 times the upper limit of normal for age or a 2-fold increase in baseline creatinine

Hepatic

• Total bilirubin ≥ 4 mg/dL (not applicable for newborn) OR

• ALT 2 times the upper limit of normal for age
Acute respiratory distress syndrome must include a Pao\textsubscript{2}/Fio\textsubscript{2} ratio < 200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically except that the Pao\textsubscript{2}/Fio\textsubscript{2} ratio must be < 300 mm Hg.

Proven need assumes oxygen requirement was tested by decreasing flow if required.

In postoperative patients, this requirement can be met if the patient has developed an acute inflammatory or infectious process in the lungs that prevents him or her from being extubated.

ALT = alanine transaminase; GCS = Glasgow Coma Scale.

The relative ability of infants and children to augment CO through increased heart rate, as seen in adults, is limited by their preexisting elevated heart rate, which precludes proportionate increases in heart rate without compromising diastolic filling time. In addition, in adults, ventricular dilation is a compensatory response used to maintain CO. However, the increased connective tissue content of the infant’s heart and the diminished content of actin and myosin limit the potential for acute ventricular dilation.

Neonatal septic shock can further be complicated by the physiologic transition from fetal to neonatal circulation. Sepsis-induced acidosis and hypoxia can increase pulmonary vascular resistance and thus arterial pressure, thereby maintaining the patency of the ductus arteriosus. This results in persistent pulmonary hypertension (PPHN) of the newborn and persistent fetal circulation. Neonatal septic shock with PPHN will increase the workload on the right ventricle, leading to right ventricular failure, tricuspid regurgitation, and hepatomegaly. Therefore, therapies directed at reversing right ventricular failure by reducing pulmonary artery pressures are commonly needed in neonates with fluid-refractory septic shock and PPHN. The treatment of PPHN will not be discussed in this chapter.

**INITIAL MANAGEMENT**

Since the landmark study by Rivers in 2001\textsuperscript{9} showed a 33% reduction
in mortality in adult patients with sepsis when patients were aggressively treated with early fluid resuscitation, early red cell transfusion, and early inotropic therapy within 6 hours of presentation, goal-directed therapy has been advocated for patients who present in septic shock. Although aggressive interventions to allow for optimization of oxygen delivery (e.g., placing central lines to measure central venous pressure [CVP] or mixed venous oxygen saturation [Svo₂]) are no longer recommended, the components of early goal-directed therapy include prompt resuscitation of poor perfusion through the administration of intravenous fluids and appropriately targeted inotropic and/or vasopressor therapy, early empiric antimicrobial therapy, drainage of infection, and appropriate and continuous monitoring of hemodynamic status.⁵,⁹-¹²

In addition to goal-directed therapy, support of the airway and breathing is essential to optimize oxygen delivery. Supplemental oxygen should be administered to all patients presenting with signs of septic shock, and endotracheal intubation may be necessary. Because goal-directed therapy includes aggressive fluid resuscitation, early and immediate vascular access is essential to the treatment of septic shock. Ideally, two peripheral intravenous catheters should be placed promptly. Intraosseous access should be considered in any patient for whom peripheral vascular access is not rapidly established. Although ideal, a central venous line is not required for initial fluid resuscitation.

All patients with septic shock have some degree of hypovolemia because of many factors, including increased insensible losses (i.e., excessive sweating, fever, and increased respiratory rate), excessive fluid losses from diarrhea or vomiting, third spacing of fluid caused by capillary leak, and diminished oral intake. Relative hypovolemia occurs because of systemic vasodilation.

With the exception of the FEAST trial in Africa discussed earlier, no data suggest a difference in the survival rates of pediatric patients after resuscitation with colloids (blood products) compared with crystalloid fluids.²⁴ The choice of fluid is less important than the volume administered. Adequate volume is necessary to sustain cardiac preload, increase stroke volume, and improve oxygen delivery.
Crystalloids and colloids, specifically packed red blood cells, have equal effects on improving stroke volume. In addition, both restore tissue perfusion to the same degree if they are titrated to the same level of filling pressure.

The optimal hemoglobin for patients in septic shock has not been established. In the early management of sepsis in adults, maintaining hemoglobin concentrations of 7–9 g/dL to improve oxygen-carrying capacity has been documented to improve sepsis survival by improving tissue perfusion. Anemia in sepsis has been associated with increased mortality, but so has the administration of blood. Therefore, according to the limited data available, the Society of Critical Care Medicine has recommended that hemoglobin concentrations be maintained at 8–10 g/dL with the understanding that data for this practice are limited. Because pediatric data are limited, it is appropriate to extrapolate from the adult literature of maximizing tissue oxygen delivery if there is evidence of poor tissue perfusion. Once tissue hypoperfusion, acute hemorrhage, or lactic acidosis has resolved, red cell transfusion should be administered only when hemoglobin concentrations are less than 7 g/dL with a target goal of 8–10 g/dL. Fresh frozen plasma may be infused to correct abnormal prothrombin time (PT) and partial thromboplastin time (PTT) values, but fresh frozen plasma should not be pushed because it may produce acute hypotensive effects because of vasoactive kinins and high citrate concentrations. Finally, there is no literature to suggest that 5% albumin administration improves outcome with respect to sepsis mortality. Albumin administration may be considered in patients who are hypoalbuminemic, but routine use of albumin is not recommended.

As described previously for the management of hypovolemic shock, patients with septic shock should be reassessed for signs of improved perfusion using clinical criteria such as reduction in heart rate, improvement in blood pressure, capillary refill, quality of pulses, and mental status with each fluid bolus. If the clinical signs of shock persist, another 20 mL/kg of isotonic fluid should be administered, reaching, if necessary, 60 mL/kg within the first 15–30 minutes of treatment. Some children with septic shock require as much as 200 mL/kg in the
first hour. The results of the FEAST trial have raised the question of whether certain patient populations with shock may be harmed by the administration of aggressive intravenous fluid. This question remains to be answered.

Patients remaining in shock despite fluid resuscitation are given inotropic support to attain normal blood pressure for age and capillary refill time of less than 2 seconds. Every hour that goes by without implementing these therapies is associated with a 1.5-fold increased risk of mortality. Patients who do not respond rapidly to initial fluid boluses or those with insufficient physiologic reserve should be considered for invasive hemodynamic monitoring. Invasive monitoring of CVP is instituted to ensure that the satisfactory right ventricular preload is present, typically using a goal of 10–12 mm Hg, and that oxygen-carrying capacity is optimized by packed red blood cell transfusion to correct anemia to a goal hemoglobin concentration greater than 7 g/dL.

Fluid-refractory shock is defined as the persistence of signs of shock after sufficient fluids have been administered to achieve a CVP of 8–12 mm Hg and/or signs of fluid overload, as evidenced by new-onset rales, increased work of breathing and hypoxemia from pulmonary edema, hepatomegaly, or a diminished mean arterial pressure (MAP). Diuretics and peritoneal dialysis/continuous renal replacement therapy are indicated for patients who develop signs and symptoms of fluid overload.

Up to 40% of CO may be required to support the work of breathing; therefore, in the presence of respiratory distress, an elective tracheal intubation followed by mechanical ventilation will contribute to redistributing blood flow away from respiratory muscles toward other vital organs. Mechanical intubation, however, is not without adverse effects. It is imperative that the patient receive adequate fluid resuscitation before the intubation because the change from spontaneous breathing to positive pressure ventilation will decrease the effective preload to the heart. Ventilation may reduce the left ventricular afterload that may be beneficial in patients with low cardiac index and high SVR. In addition, ventilation may allow an alternative method to
alter acid-base balance. If sedatives and analgesics are used for intubation, it is critical to choose agents that do not cause further vasodilation. Although laboratory studies rarely affect the management of septic shock in the first hour of therapy, patients should have laboratory studies sent routinely, assessing for hematologic abnormalities, metabolic derangements, or electrolyte abnormalities that may contribute to morbidity. A peripheral white blood cell count may aid in the choice of broad-spectrum antibiotics, whereas hemoglobin and platelet count will help assess the need for early blood transfusion. A type and screen should be sent to the blood bank to prepare for any necessary transfusions. Electrolyte abnormalities are common in sepsis; recognition and treatment of metabolic abnormalities such as hypoglycemia and hypocalcemia will improve outcome. A disseminated intravascular coagulation panel, including PT, PTT, and fibrinogen, will aid in assessing the severity of illness. If abnormalities exist, they may need to be corrected before performing invasive procedures. Finally, an arterial or venous blood gas will determine the adequacy of ventilation and oxygenation and the severity of acidemia.

Unfortunately, clinical response to fluid resuscitation is a relatively insensitive indicator of the completeness of restoration of microvascular blood flow. The success of adequate fluid resuscitation can be guided by additional parameters: invasive blood pressure monitoring, CVP, measurement of Svo₂, measurement of blood lactate, and urine output. An elevated serum lactate concentration suggests that tissue is hypoperfused and undergoing anaerobic metabolism, even in patients who are not hypotensive. Because low CO is associated with increased O₂ extraction, Svo₂ can be used as an indirect indicator of whether CO is adequate to meet tissue metabolic demand. If tissue oxygen delivery is adequate, Svo₂ should be greater than 70%.

In the goal-directed study by Rivers, the patients in whom maintaining an Svo₂ greater than 70% using blood transfusion to a hemoglobin concentration of 10 g/dL and inotropic support to increase CO had a 40% reduction in mortality compared with patients in whom only MAP and CVP were monitored. This finding in children with septic shock was
reproduced by de Oliveira, reducing mortality from 39% to 12% when directing therapy to a goal Svo$_2$ greater than 70.$^{13}$

**CARDIOVASCULAR DRUG THERAPY**

Pharmacologic support in children with septic shock must be individualized because different hemodynamic abnormalities exist in pediatric patients, and the primary hemodynamic abnormalities may change with time and progression of the patient’s disease. Twenty percent of children present with predominant vasodilatory shock, called “warm” shock. This form of shock is associated with vasodilation and capillary leak, but normal or elevated CO. The patients have strong pulses, warm extremities, good capillary refill, and tachycardia. In warm shock, using a vasopressor such as dopamine, norepinephrine, phenylephrine, or vasopressin to promote vasoconstriction would be of most benefit. Fifty-eight percent of children present with “cold shock,” or predominantly a poor CO state. Clinically, this manifests as weak pulses, cool extremities, slow capillary refill, and hepatic and pulmonary congestion. Using an inotrope (e.g., dobutamine, epinephrine, or milrinone) with or without a vasodilator would be most beneficial in cold shock. Careful assessment of clinical response is critical because a combination of vasodilatory and cold shock with a low SVR and poor CO can occur in 22% of children.

**Dopamine**

In shock unresponsive to initial fluid resuscitation, the initial vasopressor of choice is dopamine, according to the pediatric advanced life support guidelines.$^4$ Dopamine has direct and indirect effects on dopamine receptors, α-receptors, and β-receptors on both the heart and the peripheral vasculature. One of the mechanisms of dopamine action is improvement in endogenous catecholamine release. In severe septic states, presynaptic vacuoles may be depleted of norepinephrine, which may explain why dopamine may have diminished activity. In addition, infants younger than 6 month may not have developed their component
of sympathetic innervations; therefore, they have reduced releasable stores of epinephrine.\textsuperscript{11}

Dopamine should be initiated at 5 mcg/kg/minute and titrated in increments of 2.5 mcg/kg/minute every 3–5 minutes until the goal of improved perfusion, blood pressure, or both is achieved.\textsuperscript{4} The maximum recommended dopamine dose is 20 mcg/kg/minute; doses higher than 20 mcg/kg/minute may contribute to increased myocardial oxygen demand without much improvement in vasopressor activity. Dopamine-resistant shock is diagnosed after titrating dopamine to 20 mcg/kg/minute with the persistence of signs and symptoms of shock. At this point, the patient should be reassessed. Measure the patient’s hemoglobin, and administer packed red blood cells to improve the hemoglobin to 8–10 g/dL. This may improve tissue oxygenation. Measure CVP to assess intravascular volume status with the goal of achieving a CVP of 8–12 mm Hg; $S\text{vo}_2$ can be used as a marker of CO (if the hemoglobin concentration is within the normal range), together with the clinical examination. Dopamine-resistant shock commonly responds to epinephrine or norepinephrine.

A recent double-blind, prospective, randomized controlled trial evaluated dopamine versus epinephrine as the initial vasoactive drug for pediatric septic shock in 120 pediatric patients (63 dopamine; 57 epinephrine). There were 17 deaths (14.2%): 13 (20.6%) in the dopamine group and 4 (7%) in the epinephrine group (p=0.033). Early administration of epinephrine appeared to be associated with increased survival in this population. However, dopamine was dosed at 5–10 mcg/kg/minute (the low end of the dosing range) and epinephrine at 0.1–0.3 mcg/kg/minute. The dosing of epinephrine could be considered more aggressive; thus, the two treatment arms are not comparable. More studies are needed before epinephrine is considered the drug of choice in children.\textsuperscript{28}

Recent adult data analyses raise the concern of increased mortality with dopamine use. One possible explanation is dopamine’s ability to reduce the release of hormones such as prolactin from the anterior pituitary gland through stimulation of the dopamine DA\textsubscript{2} receptor, thus reducing cell-mediated immunity and inhibiting thyrotropin-releasing
hormone release, worsening the impaired thyroid function known to occur in critical illness. For these reasons, some clinicians prefer low-dose epinephrine or norepinephrine as a first-line agent for fluid-refractory hypotensive hyperdynamic shock.\textsuperscript{10}

**Epinephrine**

Epinephrine is a direct agent that is naturally produced in the adrenal gland and is the principal stress hormone with widespread metabolic and hemodynamic effects. It has both inotropic and chronotropic effects. Epinephrine is a reasonable choice for the treatment of patients with low CO and poor peripheral perfusion because it increases heart rate and myocardial contractility.\textsuperscript{25} Depending on the dose administered, epinephrine may exert variable effects on SVR. At low doses (less than 0.3 mcg/kg/minute), epinephrine exerts greater $\beta_2$-adrenergic receptor activation, resulting in vasodilation in skeletal muscle and cutaneous vascular beds, shunting blood flow away from the splanchnic circulation. At higher doses, $\alpha_1$-adrenergic receptor activation becomes more prominent and may increase SVR and heart rate. For patients with markedly elevated SVR, epinephrine may be administered simultaneously with a vasodilator. Epinephrine increases glucogenesis and glycogenolysis, resulting in elevated serum blood glucose concentrations. Therefore, patients receiving epinephrine infusions should have their serum glucose concentration monitored closely. Epinephrine should be initiated at 0.1 mcg/kg/minute and titrated in increments of 0.1 mcg/kg/minute every 3–5 minutes until the goal of improved perfusion and/or blood pressure is achieved.

**Norepinephrine**

Norepinephrine is a direct agent and is naturally produced in the adrenal gland. It is a potent vasopressor that redirects blood low away from skeletal muscle to the splanchnic circulation, even in the presence of decreased CO. Norepinephrine has been used extensively to elevate SVR in adults and children with sepsis. If the patient’s clinical state is
characterized by low SVR (e.g., wide pulse pressure with diastolic blood pressure less than one-half the systolic blood pressure), norepinephrine is recommended. About 20% of children with volume-refractory septic shock have a low SVR.\textsuperscript{20} In addition, in children who are intubated and receiving sedatives or analgesics, the incidence of low SVR may be higher. In patients with impaired contractility, the additional afterload imposed by norepinephrine may substantially compromise CO. In some patients with both impaired or marginal CO and decreased SVR, myocardial contractility may need to be supported by adding an agent such as dobutamine.

**Dobutamine**

Dobutamine is a nonselective $\beta_2$-adrenergic agonist that produces improved myocardial contractility, chronotropy, and some lusitropy and improved myocardial relaxation. Its $\beta_2$ activity can lead to peripheral vasodilation, which must be considered before using it in a patient who may already be hypotensive. If hypotension does exist, dobutamine should be used in combination with other vasopressor therapy. Thus, dobutamine should be considered in the patient who has signs and symptoms or laboratory values consistent with poor tissue perfusion, but with an adequate blood pressure to tolerate some degree of vasodilation. Dobutamine should be initiated at 2.5 mcg/kg/minute and titrated in increments of 2.5 mcg/kg/minute every 3–5 minutes, to a maximum infusion rate of 20 mcg/kg/minute. Careful attention to the patient’s blood pressure is critical. Improved perfusion, decreased lactate, and increased Svo$_2$ will help determine appropriate dosing.

**Vasopressin**

Although not a recommendation in the 2015 pediatric advanced life support guidelines, vasopressin has been suggested as an alternative therapy for refractory cardiac arrest or hypotension caused by a low SVR in children whose epinephrine infusion exceeds 1 mcg/kg/minute.\textsuperscript{4} Vasopressin exerts its hemodynamic effects by the V1$\alpha$ receptor,
promoting an increase in intracellular calcium in the peripheral vasculature, thus enhancing vasoconstriction and restoring systemic vascular tone. In a preliminary case series, vasopressin at a dose of 0.3–2 milliunits/kg/minute (18–120 milliunits/kg/hour) improved blood pressure and urine output in patients with catecholamine-refractory, vasodilatory shock and allowed weaning of catecholamines once treatment was initiated. In a more recent analysis by the American Heart Association, however, vasopressin use was associated with a lower rate of return to spontaneous circulation. The use of vasopressin in critically ill children remains controversial.

**Vasodilators**

Vasodilator medications are occasionally required in the treatment of pediatric patients with sepsis having markedly elevated SVR and normal or decreased CO. Vasodilators decrease SVR and improve CO by decreasing ventricular afterload. Nitroglycerin or nitroprusside may be used for this indication. Each has a short half-life; therefore, if hypotension occurs, the agent can rapidly be reversed by stopping the infusion. Both drugs can be infused at an initial rate of 0.5 mcg/kg/minute and titrated in increments of 0.5 mcg/kg/minute to a maximum infusion rate of 5–10 mcg/kg/minute. If nitroprusside is used, it is necessary to observe for sodium thiocyanate accumulation in the setting of renal failure and cyanide toxicity with hepatic failure or with prolonged infusions (greater than 72 hours) of more than 3 mcg/kg/minute. If the patient has tolerated infusions of nitroglycerin or nitroprusside, switching to the longer-acting agent milrinone should be considered.

Milrinone is a phosphodiesterase type 3 inhibitor that produces its hemodynamic effects by inhibiting the degradation of cyclic AMP in smooth muscle cells and cardiac myocytes. Phosphodiesterase type 3 inhibitors work synergistically with catecholamines, which produce their hemodynamic effects by increasing the production of cyclic AMP. Milrinone is useful in the treatment of patients with diminished myocardial contractility and output and decreased systemic
The concern with milrinone is its long half-life (2–6 hours); milrinone takes several hours to reach steady state. To achieve rapid serum concentrations, a loading dose of 50 mcg/kg administered over 10–30 minutes is recommended. This must be done with caution in patients with sepsis and shock because it may precipitate hypotension, requiring volume infusion, vasopressor infusion, or both. Administering the loading dose over several hours may avoid this adverse effect.

**Corticosteroids**

Although adjunctive corticosteroid therapy in patients in septic shock has not made a significant difference in outcome in any of the studies published to date, replacement may be of benefit in some patients. In a recent study, 77% of children with septic shock admitted to two PICUs for 6 months had adrenal insufficiency. Because of the limited evidence of their efficacy and safety in children, corticosteroids should be reserved for children with catecholamine-resistant shock, severe septic shock, and purpura; those who have previously received steroid therapies for chronic illness; those with pituitary or adrenal abnormalities; and those who previously received etomi-date. Assessment of serum cortisol should be used to guide treatment. There are no strict definitions, but adrenal insufficiency in adults with catecholamine-resistant shock has been defined as a random cortisol concentration of less than 18 mcg/dL or an increase in cortisol of 9 mcg/dL or less at 30 or 60 minutes after an adrenocorticotropic hormone stimulation test. Similar values have been recommended for assessing serum cortisol in children with septic shock. Published guidelines for hemodynamic support of pediatric and neonatal patients with septic shock recommend hydrocortisone 0.5–1 mg/kg intravenously every 6 hours (maximum 50 mg per dose). As an alternative, some clinicians use a hydrocortisone regimen of a 50-mg/m² loading dose, followed by the same dose (50 mg/m²) divided into four doses and given every 6 hours (maximum 50 mg per dose).
SEPSIS SUMMARY

The outcome of sepsis and septic shock depends on implementing time-sensitive goal-directed therapies. Early recognition of septic shock is critical to initiating rapid aggressive fluid resuscitation. Concurrent with the administration of oxygen, diagnosis of the source of the infection should be attempted and appropriate antibiotics administered within 1 hour of presentation. Vasopressor administration should be initiated if signs of shock persist despite adequate volume administration. If signs of shock persist, packed red blood cells should be administered to maintain hemoglobin at 8–10 g/dL. Frequent assessment, both clinical and laboratory, needs to be performed to allow adjustments in vasopressor and/or inotropic therapy, depending on the clinical presentation and ongoing physiologic derangements. Using a central venous catheter for measuring CVP and Svo₂ can help guide therapy.

RESPIRATORY DISTRESS

Respiratory distress, related to problems at all levels of the respiratory tract from the nose to the lungs, is a common occurrence in children. The nose provides almost half the total airway resistance in children. Infants younger than 2 months are obligate nasal breathers, and their nose is short, soft, and small with almost circular nares. The nares will double in size from birth to 6 months, but they can easily be occluded from edema, secretions, or external pressure. Simply clearing the nasal passageways with saline and bulb suctioning can significantly improve an infant’s respiratory condition. Other physiologic reasons for a high incidence of respiratory failure in infants and children are small and collapsible airways, an unstable chest wall, inadequate collateral ventilation for alveoli, poor control (tone) of the upper airway (particularly during sleep), tendency for the respiratory muscles to fatigue, reactivity of the pulmonary vascular bed (increased sensitivity of the vasculature, particularly in young infants), inefficient immune system, genetic disorders or syndromes, and residual problems related to premature birth such as bronchopulmonary dysplasia.
The most common reason for hospital admission in the first year of life is respiratory distress. This can be explained by the many physiologic differences seen in an infant. Although all the conducting airways are present at birth and the airway branching pattern is complete, the airways are small. The airways will increase in size and length throughout childhood. As the airways increase in size, the incidence of respiratory distress will decrease. Not only are the airways smaller in an infant, but also the supporting airway cartilage and elastic tissue are not developed until the child is of school age. For these reasons, the child’s airways are susceptible to collapse and may easily become obstructed as a result of laryngospasm, bronchospasm, and edema or mucus accumulation. Normal airway resistance is highest in infants because it is inversely proportional to $1/\text{radius}$. Therefore, any airway narrowing from bronchospasm, edema, or mucus accumulation will significantly increase the airway resistance and the infant’s work of breathing. The cartilaginous ribs of the infant and young child are twice as compliant as the bony ribs of the older child or adult. During episodes of respiratory distress, the infant’s chest wall will retract further than will that of a patient with a bony rib cage. This will reduce the patient’s ability to maintain functional residual capacity or increase tidal volume, thus further increasing the patient’s work of breathing.

The respiratory muscles consist of muscles of the upper airway, lower airway, and diaphragm. They contribute to the expansion of the lung and the maintenance of airway patency. Lack of development of the small airway muscles may render young infants less responsive than older children to bronchodilator therapy. Finally, the intercostal muscles are not fully developed until school age, so they act primarily to stabilize the chest wall during the first years of life. Because the intercostal muscles have neither the ability nor the strength to lift the rib cage in the young child, the diaphragm is responsible for generating tidal volume. Therefore, anything that impedes diaphragm movement, such as a large stomach bubble, abdominal distension, or peritonitis, can result in respiratory failure in the young child.

To assess a patient for respiratory distress, four areas should be
evaluated: respiratory rate and effort, work of breathing, quality and magnitude of breath sounds, and mental status. Normal respiratory rates and definitions of respiratory distress vary with age (Table 44.7). A respiratory rate greater than 60 breaths/minute is abnormal in a child of any age but is of greatest concern in an older child. An abnormally slow or decreasing respiratory rate may herald respiratory failure. Inter-, sub-, and supracostal retractions increase with increasing respiratory distress. Although increased retractions are seen in infants, the efficiency of respiratory muscle function is decreased during the first years of life; therefore, the benefit in infants is reduced. Decreasing respiratory rate and diminished retractions in a child with a history of distress may signal severe fatigue. Nasal flaring is an effort to increase airway diameter and is often seen with hypoxemia. In addition, some infants will have an expiratory grunting noise. This noise is produced by children's involuntary effort to counter the loss of functional residual capacity by closing their glottis on active exhalation. Grunting produces positive end-expiratory pressure in an effort to prevent airway collapse. An expiratory grunt is classically seen in the presence of extensive alveolar pathology and is considered a sign of serious disease.

Among the many causes of respiratory distress in infants and children, the most common are infectious diseases, asthma,
malignancies, trauma (both accidental and non-accidental), poisonings, foreign body aspiration, anatomic upper airway obstruction, cardiogenic shock, and untreated left-to-right intracardiac shunts. Respiratory syncytial virus is among the most common causes of respiratory distress in infants and young children, leading to an estimated 90,000 hospitalizations each year.\textsuperscript{33} However, only 7%–10% of infants admitted to the hospital for RSV will be admitted to the PICU. Although RSV can occur at any age, it is severest in children younger than 2 years. Prematurity, as well as chronic respiratory disease and congenital heart disease, increases the risk of severe RSV bronchiolitis requiring hospitalization. Unfortunately, there is no pharmacologic treatment for RSV. Treatment in the intensive care unit (ICU) is supportive care and intubation and mechanical support when necessary.

Oxygen should be administered immediately in any patient when respiratory difficulty is suspected. Infants and children consume 2–3 times more oxygen per kilogram of body weight than do adults under normal conditions and even more when they are ill or distressed. The specific indications for intubation in infants and children are as follows:

- **Apnea**
- **Acute respiratory failure** (\(\text{Pao}_2\) less than 50 mm Hg in patients with fraction of inspired oxygen [\(\text{Fio}_2\)] greater than 0.5 and \(\text{Paco}_2\) greater than 55 mm Hg acutely)
- **Need to control oxygen delivery**, with institution of positive end-expiratory pressure or to provide accurate delivery of \(\text{Fio}_2\) greater than 0.5
- **Need to control ventilation** to decrease work of breathing, control \(\text{Paco}_2\), or administer neuromuscular blocking agents
- **Inadequate chest wall function**, as in patients with neuromuscular disorders such as GuillainBarré syndrome, spinal muscular atrophy, or muscular dystrophy
- **Upper airway obstruction**
Protection of the airway for patients whose protective reflexes are absent, such as those with head trauma

**MEDICATIONS FOR INTUBATION AND MECHANICAL VENTILATION**

After the decision is made to proceed with intubation, the next decision needs to be whether pharmacologic agents are appropriate. Most pediatric patients require sedation before laryngoscopy and intubation. The goal is to depress the infant’s or child’s level of consciousness sufficiently to produce appropriate conditions for intubation. Pharmacologic therapy is used to produce adequate sedation, analgesia, and amnesia plus a blunting of the physiologic response to airway manipulation. Intubation in the awake state can elicit protective reflexes that trigger tachycardia, bradycardia, and elevation in blood pressure; increased intracranial pressure (ICP), intraocular pressure; cough; and bronchospasm. Pharmacologic control promotes a smoother intubation with less physiologic stress for the patient who often is already in a compromised state. Ideally, this should be accomplished while producing minimal hemodynamic compromise.\(^{34}\)

Many factors should be considered when choosing agents for intubation: the agent’s onset of action, the patient’s hemodynamic status, the need to prevent increased intraocular or intracranial pressure that may be caused by intubation, and whether the stomach is full or empty. A wide variety of medications may be used for pediatric sedation, each with its own risk and benefits (Table 44.8).\(^{34}\) In general, agents that act rapidly and are eliminated quickly are ideal. Often, drug choices are made according to the clinician’s experience with a particular drug and the immediate availability of the drug. More importantly, the drug regimen chosen must be according to the patient’s physiologic state. Agents with adverse effects that would exacerbate any underlying medical conditions must be avoided. Narcotics used in combination with anxiolytics are commonly used.

Patients with inadequate relaxation despite adequate sedation may require neuromuscular blockade, although these agents are not without
risk. In a patient with a partial airway obstruction, neuromuscular blockade may worsen pharyngeal collapse, potentially resulting in complete airway obstruction. Therefore, neuromuscular blocking agents should only be used if the clinician is certain that adequate ventilation can be provided or that the patient can be intubated. If adequate chest rise and oxygen saturation cannot readily be maintained with bag-mask ventilation, neuromuscular blockers should not be used. Infants and children younger than 5 years have a high vagal tone and are therefore more likely to have bradycardia when intubated. Instrumentation of the airway can directly stimulate vagal receptors and induce bradycardia. In these patients, it is prudent to administer atropine 0.02 mg/kg (minimum 0.1 mg) before intubation to blunt the autonomic response. Lidocaine (1–1.5 mg/kg per dose with a maximum dose of 100 mg) may be administered intravenously to blunt the airway protective reflexes elicited by instrumentation. This may be particularly useful in a patient with elevated ICP.

In the patient with asthma, drugs that release histamine (e.g., morphine or atracurium) and have the potential to produce laryngospasm or bronchospasm should be avoided. The beneficial bronchodilatory adverse effects of ketamine, however, make it a useful choice in these patients. In a child with increased ICP, the choice of pharmacologic agent depends on the patient’s hemodynamic status. Pentobarbital is an excellent choice in the hemodynamically stable patient, whereas etomidate is preferred if the patient is unstable or hypovolemia is suspected. Etomidate should not be used routinely in pediatric patients because a single dose administered for intubation has the potential to produce adrenal inhibition. In children and adults with septic shock, etomidate administration is associated with a higher mortality rate. In all intubation, preoxygenation is carried out to increase the available oxygen in the lungs during the procedure, thus giving the practitioner some buffer time to intubate the patient. However, in patients with an elevated ICP or pulmonary vascular hypertension, hyperventilation is recommended to produce hypocarbia also.

In an infant or child with a full stomach, the risk of aspirating gastric
contents is high. Rapid sequence intubation is used when there is an aspiration risk, such as in the child with a full stomach, and there is no concern of a difficult intubation. The goal of rapid sequence intubation is to gain airway control with an endotracheal tube (ETT) as quickly as possible to prevent aspiration. The patient is preoxygenated by facemask; bag-mask ventilation should not be used because it causes gastric distension. Once all necessary intubation equipment is ready, rapidly acting sedative, analgesic, and paralytic medications are administered simultaneously. An end-tidal CO\textsubscript{2} detector should be attached to the ETT after intubation to confirm proper placement in the trachea. Colorimetric end-tidal CO\textsubscript{2} devices change from purple to yellow to confirm the presence of exhaled CO\textsubscript{2} and tracheal placement.

Continuous infusion
Infants and children: 50–150 mcg/kg/min
Adolescents: 10–50 mcg/kg/min
Endotracheal intubation and mechanical ventilation can be painful, frightening, and anxiety provoking, especially in a young child. To improve patient comfort, relieve anxiety, and lessen the work of breathing, anxiolytics, sedatives, and analgesics are commonly administered once the patient is intubated and mechanically ventilated. Maintaining adequate sedation is essential. Selection of appropriate agents is based on the patient’s physiology. Guidelines for using continuous infusions are outlined in Table 44.9. In the paralyzed patient, neuromuscular blockade neither alters consciousness nor provides analgesia; therefore, adequate sedation and analgesia are essential. Providing effective analgesia and sedation to the pediatric patient depends on accurate ongoing efforts to assess the intensity of the
patient’s pain or anxiety. Assessing pain and anxiety in infants and critically ill children who are unable to communicate relies heavily on physiologic and behavioral responses. Several pain and sedation tools have been developed and validated specifically for use in children.\textsuperscript{41} No single standard measure gives a complete qualitative or quantitative measure. Selection of an appropriate tool is based on the child’s age, underlying medical condition, and cognition level. It is essential that these tools be used to evaluate the adequacy of the ICU sedation. Policies and procedures need to be in place for the appropriate selection and use of each tool, in addition to the training of all health care professionals to use each tool appropriately. The goal is to use the minimum amount of sedation needed to adequately sedate the intubated child while minimizing adverse effects.

**STATUS ASTHMATICUS**

Status asthmaticus or severe asthma exacerbation is defined as an acute episode that does not respond to standard treatment with short-acting $\beta_2$-agonists and corticosteroids.\(^{42}\) Status asthmaticus is a primary cause of acute illness in children and one of the top indications for PICU admission.\(^{42,43}\) The indications for ICU admission vary between institutions and may be determined by respiratory care staffing on the pediatric floor. Bronchial smooth muscle spasm, airway inflammation, and increased mucus production are the key components of an acute asthma exacerbation.\(^{42,43}\) These factors produce increased pulmonary resistance and small airway collapse leading to increased work of breathing. As the degree of airway obstruction progresses, expiration becomes prolonged, and inspiration starts before the termination of the previous expiration. This results in air trapping and the classic hyperinflation seen on chest radiography. Airway obstruction and premature airway closure lead to ventilation/perfusion mismatching\(^{44}\) and hypoxemia.\(^{45}\) Lung hyperinflation, progressive increase in lung volumes, and an increase in pulmonary vascular resistance contribute to a decrease in right ventricular preload. Pulmonary vasoconstriction caused by hypoxia and acidosis leads to an increase in right ventricular afterload, and the high negative pulmonary pressure generated during inspiration in spontaneously breathing patients with asthma causes an increase in left ventricular afterload. These changes can be observed clinically in pulsus paradoxus, which is a decrease in systolic blood pressure by more than 10 mm Hg during
inspiration. In addition, tachycardia caused by bronchodilators further reduces ventricular filling time and may further reduce CO. This is evidenced clinically as a widened pulse pressure or low diastolic blood pressure and the need for additional intravascular volume. Patients rarely require inotropic support for the cardiovascular changes observed in SA.

**EVALUATION**

Prompt and rapid evaluations of the clinical status of patients with SA are essential to determine the appropriate pharmacotherapy and levels of monitoring. A gold standard for assessing SA in children does not exist. An assessment of observed signs and symptoms can be helpful to classify the disease severity. Peak expiratory flow rates (PEFRs) or FEV$_1$ (forced expiratory volume in 1 second) is difficult to reliably perform in children with acute asthma, especially in those younger than 5 years. In children 6–18 years of age, only 64% could perform PEFRs adequately. As a result, many clinical asthma scores have been developed to quantify the child’s degree of respiratory distress. None of these clinical asthma scores has been shown to be superior to any other. However, clinical scores correlate with the need for hospitalization, need for prolonged bronchodilator therapy, and severity of the exacerbation. Clinical asthma scores are not as helpful in predicting disease progression. Scores can be used not only to choose level of care, but also to wean pharmacotherapy as the patient improves.

Measuring pulse oximetry (Sao$_2$) is an important tool to determine asthma severity combined with the patient’s physical examination. An initial Sao$_2$ less than 91% on room air or an Sao$_2$ unresponsive to oxygen treatment has been associated with the need for hospital admission. For most patients, chest radiographs are unhelpful in the emergency assessment of asthma. Children with SA often have an abnormal chest radiograph with a variety of findings: hyper/hypoinflation, atelectasis, or increased extravascular fluid. These findings rarely affect patient treatment. In a small subset of children, a
chest radiograph may be helpful: children with a temperature greater than 39°C, focal abnormalities on examination, and no family history of asthma as well as those who respond less favorably than anticipated to bronchodilator therapy. In addition, chest radiography may be warranted when there is clinical suspicion for pneumothorax, pneumomediastinum, or foreign body aspiration or after intubation.

Previously, evaluation of children with SA routinely included ABG measurement. Less invasive means of assessing respiratory status are widely available by pulse oximetry (to evaluate oxygenation) and end-tidal CO$_2$ (for evaluating ventilation).$^{50,51}$ These are simple, noninvasive methods of evaluating oxygenation and ventilation. Routine ABG measurement has also fallen out of favor because no set values for pH, Pco$_2$, or Po$_2$ are diagnostic of respiratory failure.$^{52}$ Children with acute asthma commonly have mild to moderate hypoxemia and hypocarbia or normocarbia on their initial blood gas caused by hyperventilation and ventilation/perfusion mismatch. Arterial blood gas measurement may be helpful in patients with the severest SA when a rising Pco$_2$ is worrisome, and an ABG is often predictive of respiratory failure. Once a decision is made to intubate a patient with SA, frequent ABG assessment through an indwelling arterial line is useful to follow clinical progress.

SYMPTOMS

The presentation of SA varies by severity, asthmatic trigger, and patient age. Most children with severe acute asthma present with cough, tachypnea, and increased work of breathing; use of accessory muscles; nasal flaring; and anxiety. Wheezing is a common clinical finding; however, the degree of wheezing correlates poorly with the severity of disease.$^{42}$ A noisy chest is a reassuring sign because it represents sufficient airflow to cause turbulence and vibration leading to wheezing. The presence of a silent chest because of limited airflow is an ominous sign in a patient with SA and heralds respiratory failure. Agitation or dyspnea, especially in adolescents, should be recognized as severe respiratory compromise. Other findings of impending
respiratory failure and the need for a PICU admission include disturbance in the level of consciousness, inability to speak, markedly diminished breath sounds, diaphoresis, and the inability to lie down.

**TREATMENT**

**General**

First-line treatment of acute severe asthma consists of supplemental oxygen for hypoxemia, aerosolized albuterol plus ipratropium for bronchodilation, and corticosteroids for airway inflammation and edema. Typically, these therapies are administered in the ED. Failure to improve with first-line pharmacotherapy defines the patient as having SA.

**Oxygen**

Oxygen (humidified) is the first drug of choice in all patients with acute severe asthma. Children with SA have a greater frequency of hypoxia from ventilation/perfusion mismatching than do adults because of age-related differences, including lower functional residual capacity/total lung capacity ratio, increased chest wall compliance, and higher peripheral airway resistance. Oxygen therapy is monitored by pulse oximetry with a goal $\text{Sao}_2$ greater than 92%.

**Fluids**

The need for intravenous fluid boluses should not be overlooked in children presenting with SA. These patients are often dehydrated because of poor oral intake and increased insensible fluid losses from tachypnea. In addition, the increased intrathoracic pressure from air trapping can lead to decreased venous return, and the tachycardia from bronchodilator therapy can reduce filling time, leading to decreased CO. The key is to avoid overhydration because this may lead to transpulmonary edema.
**β-Agonists**

β-Agonists remain the mainstay of therapy in SA. They produce smooth-muscle relaxation by binding to β₂-adrenergic receptors in the smooth muscles of the airways. Albuterol is the most commonly used β-agonist in the United States. It is a 50:50 racemic mixture of R-albuterol and S-albuterol. The R-enantiomer is pharmacologically active, whereas the S-enantiomer is considered inactive. Levalbuterol is the pure R-enantiomer and is a preservative-free solution. One in vitro study indicated that the S-enantiomer may exaggerate airway hyperresponsiveness and also may have a proinflammatory effect. This has not been shown clinically. In a randomized controlled trial of albuterol versus levalbuterol in children with SA, Qureshi et al. found no difference in clinical asthma score or adverse effects in children presenting to the ED with moderate to severe asthma exacerbations. Considering the increased cost and lack of clinical benefit in clinical trials, levalbuterol should not be recommended routinely for patients with SA.

Traditionally, albuterol is initially administered by intermittent nebulization at 2.5–5 mg per dose. However, administration by a metered dose inhaler (MDI) with spacer is as effective as nebulization (6 inhalations per 2.5 mg) in children who can use them correctly. The results of these studies should be evaluated carefully. Although the outcome with using an MDI was shown to be equivalent to administration by nebulization, the study personnel coached patients with the MDI and spacer to ensure adequate technique. This is not always practical in the clinical setting. For children who need more frequent doses of β-agonist, continuous nebulization (e.g., initial doses of 10 mg/hour) appears to be superior to intermittent doses and results in more rapid improvement. In addition, continuous albuterol nebulization is less labor-intensive than several intermittent doses and may be more cost-effective. A drawback of continuous therapy is that patients may be assessed less often, and adverse effects such as tachycardia, jitteriness, and hypokalemia may be more common. The maximum dose of nebulized albuterol in most studies is 40 mg/hour.
Corticosteroids

Steroid administration is recommended for all patients who lack improvement clinically after standard asthma treatment of albuterol 2.5 mg/500 mcg of ipratropium aerosolized every 20 minutes for three doses. Steroids administered in the ED can reduce hospitalization rates, return hospital visits, and relapses if continued on discharge. Steroids decrease the inflammatory response, up-regulate $\beta_2$-adrenergic receptors, and decrease microvascular permeability and mucus production. Short-term use is usually not associated with significant adverse effects. However, hypertension, hyperglycemia, and behavioral changes have been reported. The National Heart, Lung, and Blood Institute (NHLBI) guidelines currently recommend administering corticosteroids systemically rather than by the inhalation route. Oral administration can be used if the child can tolerate oral medication, but if not, intravenous medication is preferred. The NHLBI guidelines suggest that 1–2 mg/kg every 24 hours of systemic prednisone/prednisolone or methylprednisolone can be used for acute asthma (maximum 60 mg every 24 hours), but they offer no recommendations for impending respiratory failure. In a recent survey of pediatric intensivists, 66% of respondents reported using a starting dose of 4 mg/kg every 24 hours in SA in the PICU. Intensivists using 4 mg/kg every 24 hours cite clinical experience as their deciding factor. Future research is needed to determine the most appropriate corticosteroid dosage and therapy duration in this critically ill patient population.

SECOND-LINE TREATMENTS

Magnesium

For children who present with SA and lack response to initial therapies, intravenous magnesium sulfate may be considered. It works through smooth muscle relaxation secondary to the inhibition of calcium uptake leading to bronchodilation. Magnesium can also inhibit mast cell
degranulation, possibly decreasing inflammation. The NHLBI guidelines suggest a magnesium sulfate dose in children of 25–75 mg/kg per dose (maximum 2 g per dose) infused for 20 minutes. Some investigators have suggested continuous infusion to target a serum concentration of 4 mg/dL; however, well-designed clinical trials showing serum concentration–targeted therapy are lacking. Possible adverse effects are muscle weakness, hypotension, tachycardia, skin flushing, and fatigue; however, these are uncommon. If hypotension occurs, it responds to the administration of intravenous fluids.

**Terbutaline**

Intravenous β-agonists should be considered in patients unresponsive to treatment with continuous nebulization. In severe exacerbations, inspiratory flow may be too poor to allow for adequate drug delivery of albuterol to the small airways, and intravenous therapy may be necessary to effectively provide β-agonist therapy. Terbutaline is considered the drug of choice in the United States. Intravenous terbutaline, administered according to a severity-related dosing algorithm, acutely improves lung function and gas exchange and shortens hospital and ICU length of stay. Carroll and colleagues have linked β2-adrenergic receptor genetic polymorphisms with either a quicker response to β2-agonist therapy and a shorter ICU and hospital length of stay or a poor response to β2-agonist therapy and a longer ICU and hospital length of stay. The children with the poor responder genotype were significantly more likely to be African American than the more rapid responder phenotypes. The genetic polymorphism of most patients admitted to the PICU is unknown. However, in African American children whose continuous albuterol nebulization fails, treatment with a bronchodilator having a different mechanism of action may be indicated.

**Methylxanthines**

Theophylline and aminophylline act through the nonselective inhibition of
phosphodiesterase and antagonize adenosine receptors in smooth muscles and inflammatory cells. The end result is bronchodilation, improved mucociliary clearance, and down-regulation of inflammation. In critically ill children with SA admitted to the PICU with impending respiratory failure, theophylline was as effective as intravenous terbutaline. In addition, treatment with theophylline was more cost-effective than treatment with terbutaline. Therefore, theophylline should be considered for patients whose continuous albuterol therapy fails.

NONINVASIVE POSITIVE PRESSURE VENTILATION

Noninvasive positive pressure ventilation is increasingly used in the care of children with SA. In these patients, a low level of continuous positive airway pressure can maintain small airway patency, reduce premature airway closure, and reduce the work of breathing. Early intervention improves outcomes and potentially avoids intubation in this population.

HELIUM-OXYGEN

Heliox is a mixture of 60%–80% helium with 20%–40% oxygen. Because of its lower density, heliox flows through small and obstructed airways with less turbulence and resistance, reducing the work of breathing and improving oxygen delivery to the lower airways. Heliox mixtures have a high helium faction and a relatively low oxygen fraction, making the therapy useless in patients with profound hypoxia.

RESCUE THERAPIES

Intubation should be a last-resort therapy for children with SA. Intubation may aggravate bronchospasm and precipitate circulatory collapse. Next to severe hypoxia, rapid deterioration in the child’s mental status, progressive exhaustion, and cardiac and respiratory arrests are indications to intubate. Once the decision to intubate has
been made, a fluid bolus should be given to prevent the hypotension associated with positive pressure ventilation. Ketamine, because of its bronchodilatory action, is the preferred induction agent. Children may require significant amounts of sedation to avoid tachypnea and ventilator dyssynchrony. Neuromuscular blockade should be reserved for patients in whom adequate ventilation cannot be achieved at acceptable inspiratory pressures.

Despite many recent advances in the understanding of the pathophysiology of asthma, β-agonists and steroids remain the mainstay of treatment for SA. Current literature supports the use of adjuvant therapies such as magnesium as well as a resurgence in the use of methylxanthines. Noninvasive positive pressure ventilation may prevent the need for intubation. The goal in asthma is to avoid intubation, if possible. A summary of drug dosing in asthma may be found in Table 44.9.

PEDIATRIC TRAUMATIC BRAIN INJURY

Among children, traumatic brain injury (TBI) is the leading cause of mortality and leads to significant morbidity among survivors. Each year, more than 400,000 U.S. children have a TBI requiring an ED visit, resulting in 30,000 hospitalizations and 3,000 deaths. The most common mechanisms of injury differ by patient age. Children younger than 4 years usually have injuries because of child abuse, falls, and motor vehicle collisions (MVCs). Child abuse, or nonaccidental trauma (NAT), represents up to two-thirds of severe TBI cases in some series. Although it is difficult to obtain accurate data, the incidence of TBI caused by NAT in the first 2 years of life was 17 per 100,000 person-years in a population-based study from North Carolina. According to the National Center on Shaken Baby Syndrome, this translates to around 1,300 children per year in the United States who have severe head trauma from child abuse. In school-aged children 5–12 years of age, pedestrian-MVC and bicycle-related injuries are among the more common causes of severe injuries. For adolescents, MVCs replace falls as the leading cause of all injuries, followed by assault and sports-
related injuries.

The anatomic differences in the infant’s brain render it more susceptible to certain types of injuries after head trauma.\textsuperscript{66} Infants and young children have large, heavy heads. The head is unstable because of its relative size to the rest of the body. If an infant or young child falls a significant distance, is ejected during an MVC, or is thrown from a bicycle after colliding with an automobile, the head will tend to lead (i.e., the infant or child will fly head first), and severe head injuries will occur when the head ultimately strikes the ground or another object. The infant’s weak neck muscles also allow for greater movement when the head is acted on by acceleration/deceleration forces. The skull is thinner during infancy and early childhood, providing less protection for the brain and allowing forces to transfer more effectively across the shallow subarachnoid space. The base of the infant’s skull is relatively flat, which also contributes to greater brain movement in response to acceleration/deceleration forces. In addition, the infant’s brain has a higher water content (about 88\% vs. 77\% in an adult), which makes the brain softer and more prone to acceleration/deceleration injury. The water content is also inversely related to the myelination process, and the higher percentage of unmyelinated brain makes it more susceptible to sheer injuries. The infant brain is typically fully myelinated by 1 year of age. As the result of these physiologic differences, there are differences in the pathology after pediatric TBI by age group. In infants and young children, diffuse injury (e.g., diffuse cerebral swelling) and subdural hematomas are more common than the focal injury (e.g., contusions) that is typically seen in older children and adults. The typical pattern of hypoxic-ischemic injury in infants and young children after NAT is rarely seen in older children and adult survivors of abuse.

Goldstein et al. have published risk factors for NAT according to data gathered from several earlier reports.\textsuperscript{67} They found that individuals with inflicted head injury tended to be younger, were more often from families of poorer socioeconomic backgrounds, and were more likely to have parents who were younger than 18 years and who had never been married. In addition, a history inconsistent with physical findings was strongly associated with the presence of inflicted head
injury. Additional risk factors reported as associated with NAT are alcohol or drug abuse, previous social service intervention, or a history of child abuse, in combination with either retinal hemorrhages or an inconsistent history or physical examination. These investigators found that a combination of these factors was 100% predictive of child abuse in children admitted to a PICU. Nonaccidental trauma should be suspected when the injury does not meet the story (e.g., a fall of about 3 ft is required to cause significant head injury to an infant or child; a standard couch is 18 inches from the floor).68

The ability to evaluate the severity of TBI is essential to appropriately direct care, predict outcomes, and compare results to evaluate and improve patient care. Initial symptoms on presentation have little or no correlation with injury severity after TBI. The Glasgow Coma Scale (GCS) is a widely accepted method for initially evaluating and characterizing trauma patients with head injuries (Table 44.10). The scale is composed of visual, motor, and verbal components, with lower scores representing more serious injuries. The severity of TBI may be characterized as mild (GCS 13–15), moderate (GCS 9–12), or severe (GCS 3–8) on presentation; however, continued evaluation of GCS scores is the best way to track the patient’s clinical progress.69

The radiologic examination of choice for the immediate assessment of a child with severe TBI is a noncontrast cerebral computed tomography (CT) scan. Most children with severe TBI undergo immediate CT imaging to delineate their injuries as soon as they have been fully assessed and sufficiently stabilized to permit safe transport to the radiology suite. If the brain injury does not need immediate surgical intervention, the patient’s care is continued in the PICU with the implementation of therapies designed to minimize secondary brain injury. In a retrospective review of 309 children presenting with TBI, Chung et al. found that GCS scores were more useful in predicting survival among pediatric patients with TBI than were CT findings and the presence of injuries to other organ systems. In addition, they identified a GCS score of less than 5, rather than a score of less than 8 as used in adults, as the threshold at which the patient was more likely to have a poor outcome. The authors also found that head CT findings of swelling or edema and subdural and intracerebral
hemorrhage were associated with worse outcomes than subarachnoid or epidural hemorrhage.

Retinal hemorrhages are often, although not always, observed in inflicted head injury in infants and young children. These hemorrhages are the result of sheer forces disrupting vulnerable tissue interfaces. The vitreous body is adherent to the retina in early childhood; shaking can cause retinal hemorrhaging throughout several tissue layers, extending to the periphery of the retina. This pattern is unique to “shaken baby syndrome.” Although useful for diagnosis, the ocular examination is often deferred initially when evaluating an infant or child for TBI because the medications used to facilitate funduscopy will preclude the use of pupillary reactivity as a tool to monitor evolving intracranial events.

According to the American Academy of Pediatrics guidelines on imaging for NAT, a skeletal survey is strongly recommended in all cases of suspected physical abuse in children younger than 24 months. A skeletal survey consists of films of the extremities, skull, and axial skeletal images. Follow-up radiographs of the ribs to assess for healing fractures not seen in the acute phase may be helpful 2–3 weeks after the skeletal survey. As with the eye examination, the skeletal survey is often delayed until the child is more stable.

The initial treatment of a child with a head injury should focus on the basics of resuscitation: assessing and securing the airway, ensuring adequate ventilation, and supporting circulation. In addition, the treatment goals of TBI are directed toward protecting against secondary brain insults, which can exacerbate neuronal damage and brain injury. Secondary brain insults are often the result of systemic hypotension, hypoxia, hypercarbia, anemia, and hyperglycemia. Aggressive treatment strategies are needed to prevent or treat these conditions to decrease morbidity and improve neurologic outcome after TBI in children. The criteria for tracheal intubation include hypoxemia not resolved with supplemental oxygen, apnea, hypercarbia ($P_{aco_2}$ greater than 45 mm Hg), a GCS score of 8 or less, a decrease in GCS greater than 3 compared with the initial score, cervical spine injury, loss of pharyngeal reflex, or any clinical evidence of herniation. All patients
should be assumed to have a full stomach and cervical spine injury, so the intubation should be carried out with a rapid sequence intubation using appropriate short-acting sedatives and muscle relaxants.

After intubation, mechanical ventilation goals include 100% oxygen saturation, normocarbia (35–39 mm Hg), and no hyperventilation, as confirmed by ABGs, end-tidal CO$_2$ monitoring, and chest radiographs showing the tracheal tube in good position. Unless the patient has signs or symptoms of herniation, prophylactic hyperventilation (Paco$_2$ less than 35 mm Hg) should be avoided.$^{71}$ Hyperventilation causes cerebral vasoconstriction, which decreases cerebral blood flow and subsequent blood volume. Although it will lower ICP, hyperventilation may result in ischemia. Furthermore, respiratory alkalosis caused by hyperventilation makes it more difficult to release oxygen to the brain, shifting the oxygen-hemoglobin curve to the left. Short-term use of hyperventilation, however, may be useful in preventing herniation while other medical therapies are implemented. In addition to mechanical ventilation, the head of the bed should be kept in the neutral position, and jugular venous obstruction should be avoided to prevent ICP elevation. Elevating the head of the bed to 30 degrees usually decreases ICP.

Assessment and reassessment of the patient’s circulatory status, including central and peripheral pulse quality, capillary refill, heart rate, and blood pressure, is critical. Hypotension after pediatric TBI is associated with increased morbidity and mortality.$^{71}$ Initial treatment of hypotension in the child with a head injury is similar to that described earlier for pediatric shock; however, the goal systolic blood pressure in the patient with TBI is typically higher: the 50th–75th percentile for age, sex, and height or greater. Systolic blood pressure less than the 75th percentile has been associated with a 4-fold increase in the risk of poor outcome after severe TBI, even when values were 90 mm Hg or greater.$^{72}$ This suggests the possible benefit of a higher blood pressure target until ICP or cerebral perfusion pressure (CPP) monitoring is in place to guide therapy. Because of the need for higher systolic blood pressure, norepinephrine and phenylephrine, agents with greater vasopressor effects, are more commonly used in this patient population.$^{73}$
The solution of choice for intravenous maintenance fluids in children with TBI is normal saline for children older than 1 year and 5% dextrose with normal saline for infants. Because hyperglycemia is known to worsen secondary brain insults, initial intravenous fluids for children should not contain dextrose. Infants are an exception because their low glycogen stores make them prone to hypoglycemia, especially with poor oral intake. Hypoglycemia can also worsen neurologic outcome and should be avoided. Frequent assessment of blood glucose either by point-of-care testing or on an ABG is recommended.

Fever increases metabolic demands and is associated with worse outcomes after TBI. Treatment should include 15 mg/kg per dose of acetaminophen orally or rectally every 6 hours as needed and a cooling blanket, when necessary. Ibuprofen should be avoided because it may increase the risk of bleeding. Patients who are hypothermic on arrival should only be actively rewarmed if there is hemodynamic instability or bleeding thought to be exacerbated by hypothermia. Serum electrolytes and osmolarity should be monitored regularly, together with an accurate assessment of urine output. This is important to identify the development of either syndrome of inappropriate antidiuretic hormone or diabetes insipidus. Both have been reported to occur after pediatric TBI.71

One of the most significant consequences of TBI is the development of intracranial hypertension. The presence of an open fontanel or sutures in an infant with severe TBI does not preclude the development of intracranial hypertension or negate the usefulness of ICP monitoring. Intracranial pressure monitoring is recommended for any child presenting with a GCS of 8 or less.73 When possible, placement of a ventriculostomy catheter provides accurate pressure monitoring and allows for acute drainage of cerebrospinal fluid (CSF) for treatment of elevated ICP and assessment of CPP. The CPP value is calculated by subtracting the ICP from the MAP: CPP = MAP – ICP.

This value is important as an indication of blood flow and oxygen that reaches the brain. Maintaining CPP requires the optimization of MAP with fluid therapy, and if necessary, vasoactive drugs. In ICP elevation, inotropic or vasopressor agents may be used to optimize
CPP by increasing MAP, even to the point of relative systemic hypertension. In adults, a CPP of 60–70 mm Hg is usually targeted. No data correlate CPP in infants with outcome. However, pediatric TBI studies show that CPP values of 40–70 mm Hg are associated with a favorable outcome and that a CPP less than 40 mm Hg is associated with poor outcomes.74 Because infants and children normally have a lower MAP and ICP, the Society of Critical Care Medicine Pediatric Fundamental Critical Care Support course recommends the following CPP ranges: 40–50 mm Hg in infants, 50–60 mm Hg in children, and 60–70 mm Hg in adolescents.75 This is more specific than the 2003 pediatric recommendations, which recommend maintaining a CPP greater than 40 mm Hg and an “age-related continuum” of CPP of 40–65 mm Hg in infants and adolescents.71

Uncontrolled increased ICP is deleterious and must be treated aggressively as soon as possible to reduce cerebral ischemia. In this setting, the goal of any therapy is to lower ICP enough to increase CPP and improve cerebral oxygenation. All initial treatments should be reassessed for efficacy, including treatment of fever, avoidance of jugular venous outflow tract obstruction, maintenance of normovolemia and normocarbia, and provision of sedation and analgesia. Providing sedation and analgesia is of considerable importance because anxiety and pain increase ICP. If a patient has a ventriculostomy and an elevated ICP, CSF should be drained until an ICP value of 15 mm Hg is reached; it should never be drained to 0 mm Hg because edema and diffuse brain swelling could cause an obstruction in the lateral ventricles. When a ventriculostomy is in place and CSF is frequently drained, it is important to replace the CSF drained with an equal amount of normal saline. Draining of large amounts of CSF without intravenous normal saline replacement is associated with the development of hypochloremic metabolic alkalosis. In patients whose ICP drainage fails, the intervention recommended is either the addition of a vasopressor to increase systolic blood pressure or the institution of hyperosmolar therapy.

Hyperosmolar therapy may be useful in preventing the ICP from exceeding 20 mm Hg and in maintaining normal CPP. Mannitol has long
been the standard of care for managing elevated ICP. However, although extensively used since 1961 to control elevated ICP, mannitol has never been compared with placebo. Mannitol reduces ICP by reducing blood viscosity, which promotes reflex vasoconstriction of the arterioles by autoregulation, thus decreasing cerebral blood volume and ICP. This mechanism is rapid but transient, lasting about 75 minutes and requiring an intact autoregulation. It also produces an osmotic effect by increasing serum osmolarity, causing the shift of water from the brain cell to the intravascular space. Although this effect is slower in onset (15–30 minutes), the osmotic effect lasts up to 6 hours. Mannitol is a potent osmotic diuretic; osmotic diuresis should be anticipated and fluid resuscitation available to avoid hemodynamic compromise. A Foley catheter is recommended in these patients for accurate measurement of urine output. Mannitol is excreted unchanged in the urine; serum osmolarity should be maintained lower than 320 mOsm/L to avoid the development of mannitol-induced acute tubular necrosis. Mannitol is recommended at 0.25–1 g/kg per dose.

Although mannitol has traditionally been the drug of choice for reducing elevated ICP, hypertonic saline (3% sodium chloride) is gaining favor. The main mechanism of action of hypertonic saline is an osmotic effect similar to that of mannitol. Hypertonic saline has several other theoretical benefits such as restoration of normal cellular resting membrane potential and cell volume, inhibition of inflammation, stimulation of atrial natriuretic peptide release, and improvement in CO. The theoretical advantage over mannitol is that hypertonic saline can be administered in a hemodynamically unstable patient without the risk of a subsequent osmotic diuresis. Continuous infusions of 0.1–1 mL/kg/hour of hypertonic saline titrated to maintain an ICP less than 20 mm Hg have been used successfully in children. Bolus doses of 3–5 mL/kg of 3% sodium chloride have been administered over 20–30 minutes. Serum osmolality and serum sodium increase when this regimen is used, but sustained hypernatremia and hyperosmolality appear to be generally well tolerated. Hypertonic saline has been administered with a serum osmolality reaching 360 mOsm/L without adverse effects in pediatric patients. Another potential concern with the
use of hypertonic saline is central pontine myelinolysis, which has been reported with rapid changes in serum sodium. Clinical trials have shown no evidence of demyelinating disorders.

Two nonsurgical options are included in the TBI guideline: barbiturate coma and therapeutic hypothermia. Barbiturates exert neuroprotective effects by reducing cerebral metabolism, lowering oxygen extraction and demand, and alternating vascular tone. Barbiturate serum concentrations correlate poorly with clinical efficacy; therefore, monitoring of electroencephalographic (EEG) patterns for burst suppression is recommended. Burst suppression also represents near-maximum reduction in cerebral metabolism and cerebral blood flow. A pentobarbital loading dose of 10 mg/kg per dose may be administered over 30 minutes, followed by a continuous infusion of 1 mg/kg/hour. Additional loading doses, in 5-mg/kg per dose increments, may be necessary to achieve burst suppression. The primary disadvantage of barbiturate coma is the risk of myocardial depression and hypotension. In addition, the long-term effect on neurologic outcome is unknown. The TBI guideline states that high-dose barbiturate therapy may be considered in hemodynamically stable patients with salvageable severe head injury and refractory intracranial hypertension.

Posttraumatic hyperthermia is defined as a core body temperature greater than 38.5°C, and hypothermia is defined as a temperature of less than 35°C. Although most clinicians agree that hyperthermia should be avoided in children with TBI, the role of hypothermia is unclear. Potential complications associated with hypothermia are increased bleeding risk, arrhythmias, and increased susceptibility to infection. A multicenter, international study of children with severe TBI randomly assigned to hypothermia therapy initiated within 8 hours after injury (32.5°C for 24 hours) or to normothermia (37°C) was published in 2008. The study reported a worsening trend with hypothermia therapy: 31% of the patients in the hypothermia group had an unfavorable outcome, compared with 22% in the normothermia group. However, this study had several methodological problems. Although the investigators screened patients within 8 hours, the mean time to
initiation of cooling was 6.3 hours, with a range of 1.6–19.7 hours. In addition, the protocol included a rapid rewarming of 0.5°C every 2 hours so that the patients were normothermic by a mean of 19 hours or 48 hours postinjury. The investigators found that the ICP was significantly lower in the hypothermia group during the cooling period but significantly higher than in the normothermic group during rewarming. Another trial conducted in Australia and New Zealand evaluated strict normothermia (temperature 36°C–37°C) versus therapeutic hypothermia (temperature 32°C–33°C). Patients were enrolled within 6 hours of injury, and therapeutic hypothermia or strict normothermia was maintained for 72 hours. The re-warming rate was at a maximum of 0.5°C every 3 hours or slower if needed to maintain normal CPP or ICP less than 20 mm Hg. Rewarming took a median of 21.5 hours (16–35 hours) and was without complications. However, there was no difference in pediatric cerebral performance category scores between the two groups at 12 months. It is unclear whether therapeutic hypothermia lacks efficacy because patients are not cooled soon enough (median time to target temperature 9.3 hours) or because of the heterogeneous nature of TBI. The pediatric TBI guideline states that despite the lack of clinical data, hypothermia may be considered in the setting of refractory hypertension.

Decompressive craniectomy, removal of a section of skull to allow room for brain swelling without herniation, is another option for treating pediatric patients with TBI who lack response to standard therapies. A randomized trial of early decompressive craniectomy in children with TBI and sustained intracranial hypertension showed that 54% of the surgically treated patients had a favorable outcome compared with only 14% of the medically treated group. Additional case series have confirmed that patients who receive a decompressive craniectomy have improved survival and neurologic outcomes compared with patients undergoing medical management alone. However, as with barbiturate coma and therapeutic hypothermia, decompressive craniectomy is not without risk. A recent study reported an increased risk of posttraumatic hydrocephalus, wound complications, and epilepsy in children with severe TBI. Further studies are needed to
establish the timing, efficacy, and safety of this management strategy.
The pediatric TBI guideline states that decompressive craniectomy
should be considered in pediatric patients with severe TBI, diffuse
cerebral swelling, and intracranial hypertension refractory to intensive
medical management.

**POSTTRAUMATIC SEIZURES**

Posttraumatic seizures are classified as early (occurring within 7 days
after injury) or late (occurring after 7 days). In the immediate period
after severe TBI, seizures increase the brain metabolic demands,
increase ICP, and are associated with secondary brain insults.
Therefore, it is prudent to prevent posttraumatic seizures when the
patient is at the highest risk of secondary brain insults. Infants and
children are reported to have a greater risk of early PTS than are
adults. Children younger than 2 years have almost a 3-fold greater risk
of early posttraumatic seizures after TBI than do children 2–12 years
of age. In addition to age, a low GCS (8–11) has been linked with an
increased risk of early posttraumatic seizures. The pediatric TBI
guideline states that prophylactic antiseizure therapy may be
considered as a treatment to prevent early posttraumatic seizures. No
prophylactic anticonvulsant therapy is recommended to prevent late
posttraumatic seizures.\(^7\)

Most of the published studies of children have used phenytoin for
posttraumatic seizure prophylaxis. Both phenytoin and carbamazepine
have been reported to reduce the incidence of posttraumatic seizure in
adults. A large (n=813) prospective multicenter trial evaluated the
effectiveness of levetiracetam for seizure prophylaxis in adults with
severe TBI.\(^8\) Although the trial showed that levetiracetam was as
effective as phenytoin in preventing posttraumatic seizures after TBI,
the authors concluded that the significant cost difference between the
two treatments makes phenytoin the preferred therapy. There are
currently no studies of levetiracetam for posttraumatic seizure
prophylaxis in children.
STRESS-RELATED MUCOSAL BLEEDING

The use of prophylaxis to prevent stress-related mucosal bleeding, although common in adult ICU patients, is not widely used in PICUs. Studies conducted to date have provided a wide range of gastrointestinal (GI) tract bleeding rates in children, 10%–50%, with rates of clinically significant bleeding of around 1%–4%.\textsuperscript{81,82} Several investigators have identified thrombocytopenia, coagulopathy, organ failure, and mechanical ventilation as important risk factors for GI bleeding, similar to studies conducted in adults. A recent systematic review suggested that critically ill pediatric patients benefit from prophylaxis; however, the results were limited by the small number of controlled studies available.\textsuperscript{79}

There are no clear recommendations in pediatric patients for the use of histamine-2 blockers (H\textsubscript{2}-blockers) versus proton pump inhibitors (PPIs) for stress ulcer prophylaxis in the PICU. However, in 2015, a retrospective cohort analysis reviewed 336,010 PICU admissions in 42 freestanding children’s hospitals. Results showed that administering gastric acid suppressant medications, prescribed on the first day of PICU hospitalization, was common, occurring in 60% of hospitalizations. Among those receiving treatment, H\textsubscript{2}-blockers were used more often (70.4%) than PPIs (17.8%), and both types of agents were used in 11.8% of cases.\textsuperscript{83}

THROMBOSIS PROPHYLAXIS

Patients admitted to the PICU can range from newborns to young adults. Unlike in adults, there are no data on the use of subcutaneous heparin or low-molecular-weight heparins as prophylaxis to prevent deep venous thrombosis (DVT) in children. However, when children reach puberty, the hormone changes that take place appear to increase children’s risk of thrombosis compared with adults. Although no published guidelines or consensus papers currently exist to guide therapy, all pubescent adolescents should be considered for DVT prophylaxis. Most thrombosis cases in infants and young children are
associated with the long-term use of central venous catheters. Additional risk factors that have been reported in children include active inflammatory bowel disease, obesity, and infection.\textsuperscript{84,85}

Unfortunately, a study evaluating low-dose heparin infused at 10 units/kg/hour did not prevent catheter-related thrombosis in infants after cardiac surgery.\textsuperscript{86} Of note, the heparin dose used in this study was less than the anticoagulant dose recommended for infants and children (15–25 units/kg/hour). The routine use of DVT prophylaxis in children remains controversial; however, it should be considered in pubescent children.

**HYPOGLYCEMIA**

Hypoglycemia often develops in infants during episodes of stress, including shock, seizures, and sepsis. Infants have high glucose needs and low glycogen stores, which makes hypoglycemia a risk in a critically ill infant, especially one with poor enteral intake. Point-of-care glucose testing should be performed in any critically ill infant with a history of poor oral intake. The clinician should not wait to obtain serum chemistries. The aggressive fluid resuscitation recommended for hypovolemia and shock will only exacerbate hypoglycemia. More importantly, hypoglycemia needs to be prevented during cardiopulmonary and trauma resuscitation because it may cause seizures and has been linked with poor neurologic outcome.\textsuperscript{4,5} Hypoglycemia in pediatric patients must always be promptly identified and treated. After diagnosis, the patient should be treated with a bolus of 0.5–1 g/kg of glucose or 5–10 mL/kg of a 10% dextrose solution as required to achieve a serum glucose greater than 100 mg/dL. Neonates, especially premature neonates, are more prone to intraventricular hemorrhage with rapid changes in serum osmolarity than are older infants and children; therefore, 0.2 g/kg or 2 mL/kg of 10% dextrose is recommended in this population until the target serum glucose is achieved.

**CONCLUSION**
Common causes for admission to the PICU differ from causes for admission to adult ICUs. In addition, changes in physiology with normal growth and development can make the definitions of a disease differ between infants and children, as with supraventricular tachycardia, or predispose a specific age group to more severe disease. The clinician must recognize the many physiologic changes that take place during normal growth and development and understand how they affect the patient’s assessment and treatment. Pediatric health care providers practicing in critical care settings such as the ED or PICU must be adept at incorporating these physiologic differences into medication selection, dosing, and monitoring to optimize patient care.

FDA Food and Drug Administration

FDASIA Food and Drug Administration Safety and Innovation Act
INTRODUCTION: PREVALENCE AND CURRENT TRENDS

Drug shortages are a significant threat to the quality and safety of the medical care provided to critically ill patients. Despite new regulations signed into law in 2012 giving the U.S. Food and Drug Administration (FDA) more authority to help prevent shortages and enhancing collaboration between the FDA and manufacturers, shortages of commonly used medications persist. New drug shortages have decreased from their peak in 2011 (a 47%–80% decrease from 2011 to 2014, depending on the source) (Figure 45.1). However, at this time, there were more than 215 current drug shortages being tracked (Figure 45.2). About 44% of the shortages reported in 2011–2013 are of generic injectable medications, which are vital in the treatment of critically ill patients. In addition, four of the top five drug classes accounting for most shortages currently represent medications vital in the care of critically ill patients, including anesthetics/central nervous system agents, anti-infective agents, electrolytes/nutrition, and cardiovascular drugs (Figure 45.3). Some examples of generic injectable medications that have recently been on shortage include calcium gluconate, cefazolin, epinephrine, norepinephrine, piperacillin/tazobactam, and vecuronium.

Causes of Drug Shortages

The causes of drug shortages are complicated and multi-factorial. Each shortage often has its own unique causes. According to the FDA, the main cause of drug shortages is quality problems with a product or manufacturing plant such as sterility issues or the presence of particulate matter. Both of these can lead to drug recalls. The FDA cites other causative issues, including plant shutdowns to address quality issues, concentration of the drug market to a few firms, and a
lack of redundancy in manufacturing. However, the cause of an individual shortage is reported as unknown almost 50% of the time (Table 45.1).

The International Society for Pharmaceutical Engineering (ISPE) surveyed drug manufacturers in its 2013 Drug Shortages survey. Almost half of the respondents identified quality issues as a primary cause of shortages, echoing the FDA’s reports. Many of these quality issues related to equipment systems and facilities dealing with aseptic processing equipment. The issues were often the result of a mix of aging equipment and improper use of that equipment. However, ISPE noted that the most significant issue preventing maintenance or modernization of facilities is the length of time it may take to obtain proper regulatory approvals (up to 3–7 years).  

![National Drug Shortages](image)

**Figure 45.1** New drug shortages by year, January 2001 – June 30, 2015.

Reprinted with permission from: University of Utah Drug Information Service.
Since drug shortages started increasing in 2004, the FDA has improved its ability to prevent and respond to drug shortages. The FDA reported that in 2013, it helped prevent almost 80% of impending shortages.¹ Some of the success at prevention is the result of new powers granted by the FDA Safety and Innovation Act of 2012, which, among other things, require manufacturers to report discontinuations of their products 6 months in advance and allow the FDA to expedite its review of new or abbreviated drug applications that would help mitigate a shortage.⁴
IMPACT ON PATIENT SAFETY AND QUALITY OF CARE

Drug shortages have a negative impact at all levels of the health care system, including at the patient, health care professional, and institution or system level. Drug shortages may lead to patients receiving suboptimal care, patients being at an increased risk for adverse events or medication errors, treatment delays, cancellation of procedures, and patient harm.

Two surveys of several groups of health care professionals done in 2010 and 2012 showed that drug shortages have a significant impact on patient care.\textsuperscript{5,6} From 20% to 40% of respondents to each survey noted that at least one patient had experienced an adverse event at a health system because of a drug shortage. In addition, more than 50% of respondents reported that medication errors had occurred in their facilities in the past year that were directly related to shortages. Other reports have noted the more serious harms that have occurred related to drug shortages such as a greater relapse rate of patients with certain types of cancer. In 2011, 15 deaths were potentially caused by the use of substitute drugs because of a drug shortage.\textsuperscript{7,8}

Specific examples of medication errors and adverse events reported in surveys that were caused by drug shortages include the following:\textsuperscript{5}:

- Because of conservation efforts, a patient received inadequate sedation with propofol during a procedure and woke up
- Patients could not be extubated or weaned off the ventilator because of excess sedation from use of less familiar drugs
- A patient received rocuronium at the infusion rate intended for cisatracurium
- A patient received a 10-fold overdose of epinephrine during a code when there was confusion from having to stock an unfamiliar concentration of the drug
- A patient died when the patient could not receive amikacin (which was the only medication the patient’s infection was sensitive to)
Two patients died after receiving intravenous hydromorphone that was prescribed and administered at the dose intended for intravenous morphine.

In addition to direct harm to the patient, health care professionals are significantly affected by drug shortages. According to the same 2010 survey cited previously, the most common issue noted by health care professionals was the lack of timely information about a given shortage.\(^5\) Drug shortages can lead to conflict and a tense work environment, which may be related to the lack of available information, the need to use nonoptimal therapies that providers are not used to using, and the need to make tough ethical decisions in order to conserve the dwindling supply of a drug.\(^9\) There is speculation that shortages lead to changes in the training of prescribers and in prescribing patterns as prescribers become used to using a second- or third-line therapy when the first-line agent is on a long-term shortage.\(^10\) The additional time required to manage shortages may add to the fatigue of a health care worker with an already full load of responsibilities, which could lead to errors and patient adverse effects. Drug shortages also force providers to take time away from other “high-impact, high-value” tasks such as patient care, education, and research.\(^9,11\)

Finally, drug shortages have a significant financial impact. For example, the Premier Health Alliance estimated that an average of $230 million was spent annually from 2011 to 2013 across the country to purchase supplies of drugs on shortage from alternative suppliers.\(^7\) In addition to the higher purchase price, the financial burden on institutions comes from ordering an increased quantity of a drug before or during an ongoing shortage. Also contributing to the financial burden are the additional personnel costs that may be required to manage shortages and potential lost revenue because of the delay or cancellation of procedures. A 2011 survey of pharmacy directors tried to quantify the impact of drug shortages on personnel time and costs.\(^11\) The survey showed that an average of 17 hours was spent weekly on managing drug shortages. The survey also estimated that the personnel costs for managing shortages was $216 million annually in
the United States, with the cost ranging from $25,000 to $48,000 per hospital, depending on the size of the hospital. However, this figure is likely an underestimate because some health systems have hired personnel solely to manage shortages, and at the time the survey was administered, the number of drug shortages was lower than it is now.

**MANAGEMENT STRATEGIES FOR DEALING WITH DRUG SHORTAGES**

It is vital for a hospital or health system to have a clearly defined plan and process for managing drug shortages to help mitigate the related risks and costs mentioned earlier (Figure 45.4). The strategic planning to manage drug shortages has been compared with the strategic planning for an emergency weather event or mass-casualty incident. This planning and management is particularly vital for critically ill patients because generic injectables continue to be a significant portion of the drugs on shortage.

![Figure 45.3](image-url) Top 5 drug classes on shortage.
The first step in effectively managing drug shortages is to identify which medications are (or are likely to be) on shortage and gather information on the cause and expected duration of the shortage.\textsuperscript{12,13} Having someone in charge of purchasing help to identify shortages by monitoring the issues with a product in the supply chain is one place for identification to occur. In addition, there are two main websites to find details about current drug shortages.\textsuperscript{14,15} Both the American Society of Health-System Pharmacists (ASHP) and the FDA maintain online databases of current shortages together with pertinent information specific to each shortage (e.g., cause of shortage, alternative manufacturers). When researching a potential or actual shortage, it is helpful to visit both websites for details because the content may be different depending on the different ways each group defines a shortage and gathers its information. In general, the ASHP website will list more shortages and will include content directed more toward the health care professional.\textsuperscript{1,16}

After the identification of an actual or potential shortage issue, the identified individual or group in charge of managing shortages should begin assessing the potential impact. The first task of assessment is to

</tbody>
</table>
verify the current stock of the drug on hand and compare that with historic purchasing and drug use data to assess when the impact of the shortage may be felt. In addition, it is important to investigate and factor in the availability of the drug from any preapproved alternative sources, the availability and use of therapeutic alternatives, and the financial impact of ordering alternative agents. Ideally, at this point, the group in charge of managing shortages can analyze the threat to patients from a given shortage.\textsuperscript{12,13}

![Figure 45.4 Algorithm for the management of drug shortages.](image)

A plan for best mitigating the impact of the shortage should be created according to the information initially gathered. There are several different means of mitigating risks of a drug shortage, and the mitigation plan for each shortage is unique. Often, alternative sizes or concentrations are available for a drug on shortage. In some instances, it may be possible to make background operational changes within the
pharmacy such that providers prescribing or administering these agents are completely unaffected. If this is not possible, it may be necessary to decrease use of the drug by prioritizing patients, restricting the drug’s use, and ordering and using alternative drugs. In these cases, it is important to engage the pharmacy and therapeutics committee or the ethics committee of an institution to help establish and communicate clear guidelines for the drug’s use. One large academic medical center developed a policy around an ethically justifiable rationing approach for shortages.\textsuperscript{17} Regardless of the plan, communication to any potential end users is vital to help ensure that a plan remains effective for as long as necessary. Regular communication through several different venues (electronic health and prescriber order entry systems, e-mail, postings on bulletin boards in applicable places, staff meetings, and any other means that your organization uses well) will help ensure that regular communication occurs.\textsuperscript{12,13} Depending on the severity and potential ramifications of the shortage, senior medical and administrative leadership may need to be notified and engaged in supporting and disseminating any action plans.

Strong relationships and communication are vital to make the response to a drug shortage as safe and effective as possible. Although a pharmacy department may often take the lead, it is important to have relevant stakeholders, leaders, and committees from many different disciplines involved with planning and regularly providing feedback throughout the process. It may also be important to engage risk management and legal departments within an institution for a given shortage in order to help assess the impact of shortages that pose a larger threat to patient care so that they can plan accordingly. Finally, it may be helpful to build relationships with other hospitals to share information and emergency supplies.\textsuperscript{12,13}

\textbf{CONCLUSION}

Although the number of new drug shortages per year has been declining since 2012, the ongoing drug shortage problem continues to place patients, health care teams, and health care institutions at risk of
adverse outcomes. Drug shortages have several complex causes that are not quickly or easily fixed. Because of this, ongoing management with a team-based approach is necessary at the hospital level to mitigate these risks and prevent patient harm.

Chapter 46  Drug Interactions in the Intensive Care Unit

Cristian Merchan, Pharm.D.; and John Papadopoulos, Pharm.D., B.S., FCCM, BCNSP

LEARNING OBJECTIVES

1. Discuss the importance of recognizing drug interactions.
2. Differentiate between a pharmacokinetic and a pharmacodynamic drug-drug interaction (DDI).
3. Analyze specific examples of clinically significant DDIs relevant in the intensive care unit setting.
4. Explain the importance of drug-nutrient interactions.
5. Summarize an approach to evaluate the evidence of DDIs.

ABBREVIATIONS IN THIS CHAPTER

AUC  Area under the curve
DDI  Drug-drug interaction
DIPS  Drug Interaction Probability Scale
H2RA  Histamine-2 receptor antagonist
ICU  Intensive care unit
MAO  Monoamine oxidase
INTRODUCTION

The care of the critically ill patient is a complex process that requires clinicians to draw on their knowledge of pathophysiology, pharmacology, pharmacokinetics, clinical trials, and differential diagnoses. Patients cared for in an intensive care unit (ICU) environment receive several medications to treat a variety of acute and chronic ailments, as well as prophylactic medications to prevent complications such as stress-related mucosal damage and deep vein thrombosis. Each ICU clinician needs to understand the importance of drug interactions, given the complexity of pharmacologic interplay in the ICU environment, the common presence of organ dysfunction, and our heightened awareness for the need to provide optimal and safe care for our patients. Published data quantifying the magnitude of drug interactions and their effects on clinical outcomes in the ICU are limited. A single-center, prospective, observational study of 281 patients admitted to a medical ICU reported that drug interactions accounted for 4% of ICU admissions.\(^1\) Additional data analyses report that the percentage of patients in the ICU with at least one drug interaction is 40%–73%.\(^2-6\)

Several observational studies have been conducted to identify significant potential drug-drug interactions (DDIs) in a variety of ICU settings. Smithburger and colleagues conducted a prospective, observational study to identify DDIs in the cardiovascular and cardiothoracic ICUs.\(^2\) Micromedex and Lexi-Interact interaction databases were used to screen each patient’s medication profile and determine the severity of identified DDIs. Of the 400 patient medication profiles evaluated, 56% had one or more potential DDIs. The most significant DDIs were determined by assignment to the major
interaction category by just one of the interaction databases. These included drugs that can prolong the corrected QT (QTc) interval, enhance antiplatelet or anticoagulant effects, and inhibit the cytochrome P450 (CYP) 3A4 enzyme. The most common drugs cited as involved in major interactions included amiodarone, aspirin, clopidogrel, heparin, warfarin, clonidine, and β-blockers. Smithburger and colleagues also conducted a similar evaluation in the medical ICU. From the 240 patient medication profiles evaluated, 46% had one or more potential DDIs. The most significant DDIs involved medications that can enhance antiplatelet or anticoagulant effects, prolong the QTc interval, or inhibit CYP3A4 or that can be classified as an antiepileptic. The most common drugs cited as involved in major interactions included aspirin, clopidogrel, selective serotonin reuptake inhibitors (SSRIs), β-blockers, valproic acid, and posaconazole. In addition, these studies highlight the importance of considering the differences between ICU populations when developing clinical decision support systems in order to reduce alert fatigue, and the studies provide enough information to determine an appropriate risk-benefit ratio for the patient receiving the interacting drugs. Nonetheless, further data are needed to adequately determine the impact of drug interactions in the ICU environment.

Drug interactions are generally classified as pharmaco-kinetic or pharmacodynamic, depending on the underlying mechanism. A pharmacokinetic interaction occurs when one drug alters the absorption, distribution, metabolism, or elimination of another agent. These interactions can be quantified by changes in area under the curve (AUC), half-life, or peak serum concentration. A pharmacodynamic interaction changes the pharmacologic response to a drug in an additive, synergistic, or antagonistic way. This review will focus on DDIs and drug-nutrient interactions that have high clinical relevance in the ICU setting.

PHARMACOKINETIC DDIS
Absorption

The small intestine is the primary site for enteral drug absorption, except for a few drugs that are absorbed in the stomach (e.g., aspirin). Patient and drug-specific factors influence enteral drug absorption and net bioavailability in the critically ill. The clinical status of the patient is an important consideration when determining the intestine’s ability to absorb enterally administered medications. Many factors contribute to intestinal ischemic damage in the critically ill, including acute hemorrhage, cardiac and abdominal surgery, inotropic and vasopressor therapy, various forms of shock, and abdominal compartment syndrome. These factors redistribute blood flow away from the gastrointestinal (GI) tract and may prolong the time to reach peak concentrations and AUC of enterally administered medications. In addition, critically ill patients commonly receive stress ulcer prophylaxis with intravenous histamine-2 receptor antagonists (H$_2$RAs) or proton pump inhibitors (PPIs). Because many drugs are weak acids, the associated increase in gastric pH induced by the administration of gastric acid inhibitors can potentially alter the bioavailability of drugs normally absorbed through the GI tract that require an acidic medium for absorption (e.g., ketoconazole, itraconazole, dipyridamole). Furthermore, delayed gastric emptying is commonly observed in patients who have postoperative ileus, mechanical ventilation, electrolyte abnormalities, splanchnic hypoperfusion, increased intracranial pressure, or opioid and sedative medication needs. Because these parameters delay the rate of gastric emptying, they may lead to a delay in the rate of drug absorption, time to peak concentration, and onset of drug action for enterally administered medications. Another factor to consider in the critically ill is the effect of systemic inflammation on P-glycoprotein (P-gp) function. P-glycoprotein acts as an efflux pump that transports drugs back into the intestinal lumen after absorption. This efflux pump, in combination with any intestinal CYP3A4 inhibition, may substantially limit the bioavailability of drugs given enterally that are substrates for these systems. Systemic inflammation decreases the intestinal P-gp activity, which may lead to a consequential increase in the net oral
bioavailability of enterally administered medications that are substrates for these systems.\textsuperscript{10,11} Finally, the administration of enteral feeds, binders, or chelators can lead to a decrease in the AUC of select drugs. Table 46.1 provides specific examples of DDIs that affect the absorption of various medications prescribed in the ICU.

**TARGETED TREATMENT STRATEGIES FOR DDIS INVOLVING ABSORPTION**

Drug-drug interactions involving absorption can be handled in various ways. Therapeutic substitution (i.e., sucralfate or an H\textsubscript{2}RA instead of a PPI) for drugs that require gastric acidity or appropriate administration spacing in the presence of a binder or chelator may mitigate an absorption-related interaction. Use of the intravenous route of medication administration should be considered in a critically ill patient when a medication need is critical.

**P-glycoprotein (B)**

P-glycoprotein acts as a drug efflux pump that is responsible for transporting drugs from the circulation into the lumen of the small intestine, bile duct, and proximal convoluted tubule (Table 46.2).\textsuperscript{36-38} These pumps are located on the luminal membrane of the small intestine and blood-brain barrier and in the apical membranes of excretory cells such as hepatocytes and renal proximal tubule cells. The role of P-gp on the intestinal epithelial cells is to limit the cellular uptake and absorption into enterocytes, compared with its location in hepatocytes and renal tubular cells, where it enhances the elimination of drugs into the bile and urine, respectively.\textsuperscript{36-38} In addition, P-gp provides enhanced opportunities for medications to be metabolized by intestinal CYP3A4. Subsequently, there is increased contact of medications to the CYP3A4 enzymes that contribute toward biotransformation and decreased overall systemic exposure.\textsuperscript{36-38}

**Targeted Treatment Strategies for DDI Involving P-gp**
The role of P-gp in the realm of drug interactions may be limited (except for digoxin) unless there is concomitant CYP enzyme inhibition or induction (Table 46.3). If a concomitant P-gp/CYP enzyme interaction is identified, vigilance in therapeutic drug monitoring, indices of clinical end points, and signs and symptoms of toxicity needs to be used to determine the best clinical treatment course. Medication substitution, as described in the section on DDIs involving metabolism, may need to be used.

| Increased GI motility | | | |
| Metoclopramide | Cyclosporine$^{a,b}$ | Metoclopramide increased the peak and AUC of cyclosporine by 50% and 30%, respectively | Monitor and adjust cyclosporine concentrations as necessary. Monitor for signs and symptoms of cyclosporine toxicity, which may include acute kidney injury, cholestasis, or paresthesias |

| Presence of a binder or chelator | | | |
| Complex metals (calcium, aluminum, iron, magnesium) | Fluoroquinolones (ciprofloxacin and levofloxacin) and tetracyclines (doxycycline and minocycline)$^{b,d}$ | One randomized crossover study of 12 healthy volunteers reported that when either calcium carbonate or aluminum hydroxide tablets were taken 5 min before ciprofloxacin, the bioavailability was reduced by 40%-85% of the control value | Administer aluminum-, calcium-, or magnesium-containing products at least 2-4 hr before or 6 hr after the fluoroquinolone |
| | | Administer iron at least 2 hr after the fluoroquinolone; avoid sustained-release iron |
| | | Consider switching the fluoroquinolone to IV for severe infections in critically ill hospitalized patients |
| | Bile acid sequestrates (cholestyramine) | Digoxin, Levothyroxine, Oral vancomycin, Lipid-soluble vitamins, Warfarin$^{b,c}$ | Bind to various drugs and decrease their oral bioavailability |
| | | Much more likely to bind to acidic compounds than to basic compounds, but this is not an absolute because they can bind to basic medications as well (e.g., propranolol) | Separate the administration times of all oral medications by at least 2 hr before or 4 hr after the administration of bile acid sequestrants |
**DDIS AND DISTRIBUTION: DISPLACEMENT FROM A CARRIER PROTEIN**

Albumin and $\alpha_1$-acid glycoprotein are the two most common plasma proteins that bind to acidic drugs (e.g., antiepileptics, benzodiazepines) and basic drugs (e.g., lido-caine, synthetic opioids, tricyclic antidepressants [TCAs]), respectively.\(^7,^8,^46\) The extent of plasma protein binding depends on the concentration of plasma proteins, which may fluctuate in critical illness, and the affinity of the drug to the plasma protein. Albumin acts as a negative acute phase reactant, and the concentration decreases in the setting of sepsis, renal or liver failure,
burns, surgery, and malnutrition. However, $\alpha_1$-acid glycoprotein is a positive acute phase reactant in which increased concentrations are observed in inflammatory diseases, trauma, and acute myocardial infarctions.\textsuperscript{7,8,46}

Displacement of one drug by another from plasma proteins can lead to an increase in the unbound free fraction of the displaced drug; the unbound free fraction is the pharmacologically active entity. For most drugs, displacement from plasma proteins results in only minor changes in free plasma drug concentrations and resultant enhanced distribution and elimination pharmacokinetics. Thus, the altered plasma binding would not be expected to clinically influence the pharmacologic response, and dose adjustments are not usually required.\textsuperscript{7,8,46} Plasma binding displacement interactions become clinically important when the displaced medication has a narrow therapeutic index. In addition, the route of drug administration may be important for the clinical realization

In a pharmacokinetic study, linezolid 600 mg q12hr was given together with rifampin 600 mg q24hr. Concomitant administration led to a 21% decrease in linezolid Cmax and a 32% decrease in linezolid AUC. CYP3A has a small contribution (0.7%–10.5%) to linezolid clearance, which may be enhanced by rifampin.

---
of displacement interactions. In theory, clinically important displacement interactions are most likely to occur shortly after an intravenous push administration of a highly protein bound drug. This interplay may be less clinically relevant with oral administration of the same medications given that the slow rate of enteral absorption may result in slow displacement and quick equilibration of plasma concentrations. Phenytoin and warfarin are two drug examples for which protein binding displacement interactions may be realized with the coadministration of higher-affinity albumin binders. Valproic acid, sulfamethoxazole, salicylates, and ceftriaxone are examples of medications that can potentially increase the free fraction of both phenytoin and warfarin. However, the clinical significance of this interaction may be temporary and self-correcting. When the unbound concentration increases, the total clearance of either phenytoin or warfarin also increases as the liver metabolizes excess free drug, and steady state will return to the pre-displacement value. One consideration with phenytoin specifically is that a marked increase in free drug could result in a reduction clearance because phenytoin follows nonlinear pharmacokinetics. Management of albumin displacement interactions includes therapeutic drug monitoring and monitoring for signs and symptoms of phenytoin or warfarin toxicity until a new steady state is achieved.

TARGETED TREATMENT STRATEGIES FOR DDI INVOLVING DISPLACEMENT FROM A CARRIER PROTEIN

Displacement interactions tend to be transient and are usually not clinically significant. If a carrier protein displacement interaction is identified, vigilance in therapeutic drug monitoring, monitoring for the indices of clinical end points, and monitoring the signs and symptoms of toxicity needs to be used to determine the best clinical treatment course.

CYP AND ITS ROLE IN METABOLISM
The liver is the primary organ responsible for drug metabolism, followed by the GI tract, kidney, lung, integument, and blood.\textsuperscript{47-49} The liver has several sequential steps of drug elimination by metabolism and membrane transport. Phase 0 delivers drugs from the blood into the liver through a carrier-mediated uptake process.\textsuperscript{48} Once inside the metabolizing hepatocyte, drug metabolism is divided into phase I (oxidation, hydrolysis, reduction) and phase II (glucuronide, sulfate, and glycine conjugation) enzymatic reactions. Phase I reactions are mediated by the CYP enzyme system and convert a parent drug to a more hydrophilic metabolite. Phase II metabolism, not mediated by CYP, produces an inactive water-soluble product that can be readily excreted by the kidneys. Finally, phase III metabolism involves the excretion of these newly formed metabolites by transporter pumps such as MRP2, MDR1/P-gp, and BCRP at the canalicular hepatocyte membrane.\textsuperscript{48}

The most common and significant DDIs involve the CYP enzyme system. Cytochrome P450 is a family of heme-containing proteins located in the smooth endoplasmic reticulum of the hepatocytes. The CYP enzymes are also located, to a lesser extent, in the small intestine, kidneys, and lungs. The predominant CYP enzymes responsible for more than 90\% of human drug metabolism are as follows: CYP3A4 (36\%), CYP2D6 (19\%), CYP2C9 (16\%), CYP1A2 (11\%), CYP2C19 (8\%), and CYP2E1 (4\%).\textsuperscript{47-51} Other isoforms are minor contributors to total CYP activity and include CYP2B6 and CYP2J2. Individual CYP enzymes are specific to a substrate on the basis of a particular region of the drug molecule or enantiomer. Some substrates can be metabolized by more than one CYP enzyme, and these substrates can act as either an inducer or an inhibitor for these CYP enzymes.\textsuperscript{47-51}

Enzyme inhibition is divided into reversible and irreversible inhibition.\textsuperscript{8,47-51} Reversible inhibition (most common) is characterized as a dose-dependent interaction in which the substrate and inhibitor compete for the same site on the enzyme; the metabolism of the substrate is decreased. Irreversible inhibition is distinguished by the formation of reactive metabolites, which alter the conformation of the
enzyme so that the active biotransformation site is no longer functional. This type of inhibition is both dose- and duration-dependent. The onset of inhibition typically occurs as soon as the inhibitor is in contact with the enzyme, and the maximal effect can be observed after steady state of the inhibitor and affected substrate has been reached. Restoration of the CYP system after cessation of an enzyme inhibitor depends on several drug characteristics such as dose, half-life, presence of Michaelis-Menten pharmacokinetics, presence of genetic polymorphisms, and presence of organ dysfunction. Conversely, enzyme induction occurs when an inducer enhances the synthesis or reduces the breakdown of a CYP enzyme. The net effect observed is a decreased concentration or an increased biotransformation or prodrug activation of the affected substrate. The onset of induction will become apparent over several days to weeks as the amount of enzyme increases enough to change the drug clearance of the substrate; the offset occurs within a similar time interval. The maximum time of onset for enzyme induction depends on the half-life of the inducing agent and the time to steady state of the inducer. For example, when comparing rifampin and phenytoin, rifampin will reach steady-state serum concentrations quicker than phenytoin because of rifampin’s shorter half-life. It will take longer for phenytoin to induce CYP enzymes compared with rifampin, and the induction will remain detectable for a greater length of time after discontinuation as a result of phenytoin’s long half-life. Table 46.4 provides a list of CYP isoenzymes and some common ICU medication substrates, inhibitors, and inducers. Table 46.5, Table 46.6, Table 46.7, and Table 46.8 review the effects of specific disease states and DDIs with the most common CYP metabolizing enzymes.

TARGETED TREATMENT STRATEGIES FOR DDI INVOLVING METABOLISM

Many medications that are used in the care of critically ill patients are cleared by CYP hepatic biotransformation. The bedside clinician must have a thorough understanding of the principles of enzyme induction and inhibition, including the onsets and offsets of such interactions. The astute clinician needs to evaluate the circumstances of an identified DDI and the relevance and potential downstream effects. The decision to adjust any medication dosages, implement alternative pharmacotherapy, and implement any monitoring strategy must be made on a case-by-case basis. Team communication is a vital component of these decisions, with a plan to modify a treatment plan if the desired end point is not met or if an adverse event is identified.

RENAL ELIMINATION

The kidneys, through a combination of passive glomerular filtration rate, active tubular secretion, and tubular reabsorption, are vital in the elimination of medications. Glomerular filtration is a passive process by which water and small-molecular-weight (less than 60 Da) ions and molecules diffuse across the glomerular-capillary membrane into the
Bowman capsule and then enter the proximal tubule.\textsuperscript{7,8} Tubular secretion is an active process that predominantly takes place in the proximal tubule and facilitates the removal of medications from plasma into the tubular lumen. Four distinct transporters mediate this secretory process: organic anion transporters (OATs), organic cation transporters (OCTs), nucleoside transporters, and P-gp transporters.\textsuperscript{69,70} The OAT, OCT, and nucleoside transporters are uptake transporters that are located on the basolateral membrane of the proximal tubule and facilitate the entry of drugs into cells. Efflux transporters at the apical membrane of the proximal tubule enhance the removal of drugs from cells and into urine.

Renal uptake transporters are known to be associated with clinically relevant DDIs. Renal OAT1 and OAT3 are mainly involved in the secretion of acidic drugs.\textsuperscript{69,70} In general, these substrates transport endogenous compounds such as prostaglandins, folate, and urate as well as several drugs that are listed in Table 46.9. This active process is mediated by the exchange of extracellular drug for intracellular α-ketoglutarate. The only well-established inhibitor of the OAT transport system is probenecid, which may result in a 30\%-90\% reduction in total renal clearance and a significant increase in plasma exposure of drugs subject to this transporter. The OCT2 transporter is mainly involved in the secretion of basic drugs as shown in Table 46.9.\textsuperscript{69,70} This uptake process is facilitated by the proton gradient maintained at the apical membrane of proximal tubule cells, and efflux of drugs into the urine is mediated by the multidrug and toxin extrusion transporter 1 (MATE1).\textsuperscript{69,70} Many drugs can inhibit the cationic tubular secretion pathways (mainly MATE1), and several are highlighted in Table 46.9. Renal transport inhibition DDIs usually result in a less than 50\% increase in the AUC of the substrate drug. Of note, inhibition of renal transport would limit the effect on drug clearance to the fraction that is usually cleared by this route.

alleles (observed in 40% of the white population) warranted

Genetic polymorphism of the CYP2C19 enzyme: poor metabolizers contain a combination of *2 or *3 variant alleles (observed in 30% of the Asian population) Poor metabolizers of 2C19 will have decreased conversion of clopidogrel (prodrug) to its active metabolite

Genetic polymorphism of the CYP2D6 enzyme: poor metabolizers contain a combination of *3 or *4 variant alleles (observed in 20% of the African American population) Higher risk of adverse effects from opioids and neuroleptics that are CYP2D6 substrates

Tubular reabsorption of most medications occurs predominantly along the distal tubule and collecting duct. The extent of drug reabsorption is determined by urine flow rate, lipid solubility, and degree of ionization of the drug. For organic acids and bases, diffusion is inversely related to the extent of ionization because the non-ionized molecule is more lipid soluble and more likely to be reabsorbed.7,8 For instance, the acidification of urine favors the excretion of weak organic bases, whereas the alkalization of urine favors the elimination of weak organic acids. Medications that can alkalize the urine such as sodium bicarbonate and acetazolamide can enhance the elimination of weak acids such as salicylates, phenobarbital, chlorpropamide, diflunisal, and methotrexate. These principles of drug trapping may be useful in the toxicologic management of certain drug intoxications (i.e., salicylate overdose with sodium bicarbonate infusions).69,70

TARGETED TREATMENT STRATEGIES FOR DDI INVOLVING RENAL ELIMINATION

The clinical relevance of DDIs may be minimal. Possible explanations for this observation may be that few drugs mainly rely on tubular secretion for total body clearance, and the renal transport pathways
are generally low-affinity transporters. Nonetheless, DDIs involving renal elimination pathways may have implications in patients who have renal impairment or who are receiving drugs with narrow therapeutic indices (i.e., methotrexate). Therapeutic drug monitoring and vigilance for detecting adverse drug events are warranted when a known renal transport inhibitor is used concomitantly with a renal transport substrate.

</tbody>
</table>

RASS = Richmond Agitation-Sedation Scale.
PHARMACODYNAMIC DDIS

Pharmacodynamic DDIs may occur in the ICU setting when two or more concomitant medications elicit a similar pharmacologic response. This additive or synergistic interplay may result in an exaggerated pharmacologic effect and possibly an adverse drug event. Several common examples are reviewed that may be observed by clinicians across a variety of ICU settings.

Serotonin Syndrome

Serotonin syndrome is a potentially serious adverse event that can result from excess serotonergic activity at central and peripheral serotonin-2A receptors. Symptoms develop rapidly within hours of medication administration and may include altered mental status, clonus (typically greater in the lower extremities), tremor, hyperthermia, diaphoresis, tachycardia, and mydriasis.\textsuperscript{71-74}

The available literature on serotonin syndrome in the ICU is scarce and mostly limited to small case series and reviews.\textsuperscript{71-74} Factors associated with a greater risk of serotonin syndrome include increased patient age, serotonergic medication dosage, concomitant use of CYP inhibitors that can affect clearance of serotonergic medications, and renal or liver dysfunction.\textsuperscript{71-74} Severe toxicity resulting in death has occurred with combinations of monoamine oxidase (MAO) inhibitors or amphetamines and SSRIs.\textsuperscript{71-74} Table 46.10 highlights medications with clinically relevant serotonin-mediated effects.

A clinically relevant serotonergic DDI that can be seen in the ICU setting may occur with linezolid because it has weak reversible MAO-A and MAO-B inhibitory effects. The incidence of serotonin syndrome with concomitant linezolid and serotonergic agents is 0.24\%–4\% (e.g., SSRIs and serotonin-norepinephrine reuptake inhibitors [SNRIs]).\textsuperscript{76} Linezolid should be avoided in patients taking concurrent SSRIs or SNRIs, if possible. If the serotonergic drug is to be discontinued, the physician must allow at least 5 half-lives of the parent drug and any active metabolites to clear before initiating linezolid, which may not be practical in the ICU setting.\textsuperscript{76}
Targeted Treatment Strategies for Serotonergic Pharmacodynamic DDIs

Although serotonin syndrome is uncommon, it has the potential to complicate the administration of drugs commonly used in the ICU setting. When prescribing a serotonergic agent, it is important to obtain a clear history of the other drugs or herbal agents the patient has recently taken or recently discontinued. Life-threatening cases of serotonin syndrome may occur with the use of an irreversible MAO inhibitor or with combinations of high dosages of serotonergic medications. In the example discussed, if linezolid and a serotonergic agent require concomitant administration and the benefits seem to outweigh any risks, clinicians should consider avoiding initiation of any additional serotonergic agents to the patient’s medication regimen. It is then important to monitor for signs and symptoms of serotonin syndrome and to discontinue linezolid and other serotonergic agents if signs or symptoms develop.

Prolonged QT Interval Syndromes

Prolongation of the QT interval can predispose patients to a life-threatening polymorphic ventricular tachycardia called torsades de pointes (TdP). A threshold of QTc interval prolongation at which TdP is certain to occur is not well defined. To highlight this point, a prospective, observational study of patients admitted to a cardiac
critical care unit showed that 28% (n=251 of 900) of patients had a prolonged QT interval on admission, and 35% of these patients were administered a QT interval–prolonging medication during their ICU stay. Torsades de pointes did not occur throughout this study; the most common QT interval–prolonging medications administered were amiodarone, macrolides, and fluoroquinolones.78

Risk factors associated with a greater risk of QTc interval prolongation include age older than 65 years, female sex, hypokalemia, hypomagnesaemia, left ventricular systolic dysfunction, bradycardia, elevated plasma concentrations of QT interval–prolonging medications because of either a DDI or the absence of dose adjustment in the presence of organ dysfunction, and a history of QT interval prolongation.77,79

</table>
Drugs with the potential to precipitate TdP inhibit the rapid component of the delayed rectifier potassium current (IKr), which results in a reduction in the net repolarizing current and causes a prolongation of the ventricular action potential duration and a prolongation of the QT interval on the electrocardiogram (ECG). Medications known to prolong the QT interval include class IA and III antiarrhythmic agents, tyrosine kinase inhibitors, macrolides, fluoroquinolones, azole antifungals, prokinetic agents, antipsychotics, TCAs, antidepressants, methadone, serotonin-3 antagonists, and certain nonsedating antihistamines. However, not all QT interval–prolonging drugs (i.e., amiodarone) are associated with a risk of TdP. The low risk of TdP with amiodarone may be a result of minimized QTc dispersion, decreased early-after depolarization, and homogeneous prolongation of the action potential duration in all layers of the myocardial wall. Ranolazine is another example of a medication that may prolong the QTc interval but not precipitate TdP, probably through inhibition of late sodium currents.

Targeted Treatment Strategies to Minimize Adverse Events from QT Interval–Prolonging Medication

A thorough understanding of the risk factors for TdP and common medications that can prolong the QT interval is of paramount importance for all ICU clinicians. Care in understanding the influences of organ dysfunction and DDIs on prescribed medications is critical when these drugs are used in the ICU setting. If an identified DDI cannot be avoided, clinicians should obtain a baseline ECG and continue to monitor the effects of the drug combination with follow-up ECGs as necessary. The risk-benefit must be weighed and the patient evaluated for the potential of developing an arrhythmia when a decision is made to use QT interval–prolonging medications. Table 46.11
describes the most commonly encountered medication classes associated with QT interval prolongation and some possible management strategies.

MAOI = monoamine oxidase inhibitor.

Increased Risk of Bleeding

All anticoagulant and antiplatelet agents must be used cautiously in the ICU setting. Risk factors associated with an increased risk of bleeding include age older than 65 years, systolic blood pressure readings greater than 160 mm Hg, abnormal renal or liver function, previous stroke, a bleeding history, labile international normalized ratio (INR), use of antiplatelet agents or nonsteroidal anti-inflammatory drugs
(NSAIDs), and recent alcohol use. Medications that can increase a patient’s bleeding risk include any anticoagulant, $P_{2}Y_{12}$ inhibitors, glycoprotein IIb-IIIa inhibitors, aspirin, NSAIDs, cilostazol, dipyridamole, tissue plasminogen activator, corticosteroids, and SSRIs.\textsuperscript{84-86}

The SSRIs, and to a lesser extent the SNRIs, have been associated with an increased risk of GI bleeding, especially when used in combination with NSAIDs.\textsuperscript{87-89} The proposed mechanism is by the blockade of platelet serotonin reuptake, leading to platelet serotonin depletion and impaired platelet aggregation. In addition, animal studies have shown a dose-dependent increase in gastric acid secretion with the administration of paroxetine, sertraline, and fluoxetine, which may increase aggressive factors that can lead to GI tract damage and hemorrhage.\textsuperscript{86-89} Furthermore, fluoxetine, fluvoxamine, and paroxetine inhibit several hepatic CYP enzymes (i.e., 1A2, 2D6, 3A4, and 2C9) and can significantly increase the serum concentrations of concomitant medications that may be associated with a bleeding risk (e.g., warfarin).\textsuperscript{87-89} Because of the potential compounded platelet dysfunction associated with SSRIs or SNRIs, it is recommended to discontinue these agents in patients admitted to the ICU with GI bleeds; monitoring for SSRI or SNRI withdrawal is prudent during this time.\textsuperscript{8}

Use of the target-specific oral anticoagulants (TOACs) with antiplatelet agents is another area for potential concern.\textsuperscript{84} Published data are insufficient to guide clinical practice, and there is an element of uncertainty on how to safely use TOACs in combination with antiplatelet agents. It is highly recommended to formally assess the event and bleeding risk using the CHA2DS2-VASc and HAS-BLED scores, respectively.\textsuperscript{85,86} Table 46.12 delineates the risk associated with the combination of TOACs and anti-platelet agents according to the available literature.

**Targeted Treatment Strategies to Minimize Bleeding Risk in the ICU Setting**
Bleeding diathesis can have a significant impact in the care of critically ill patients. Clinicians need to be cognizant of the role of each anticoagulant and antiplatelet agent used and how coadministration may positively or negatively affect clinical outcomes. Concomitant administration of these agents may be warranted, especially in the context of patients who have several disease states that may include the arterial and venous vascular systems. Prescribers need to be vigilant in monitoring for evidence of clinical efficacy as well as toxicity when these agents are used clinically. Continuously evaluating the need for coadministration, assessing for DDIs with the addition of any new medications, and providing good patient communication and follow-up are key elements for the safe use of these medication classes.

</tbody>
</table>
Lower risk of TdP with azithromycin than with erythromycin or clarithromycin

**Antipsychotics**

Ziprasidone, thioridazine, and haloperidol have the greatest potential for prolonging the QT interval, followed by risperidone, paliperidone, clozapine, olanzapine, quetiapine, and aripiprazole

**Anti-nausea**

QT interval prolongation of ondansetron is dose-dependent

Single IV doses should not exceed 16 mg. Subsequent IV doses must not exceed 8 mg and must be given 4–8 hr after the initial dose. All IV doses must be infused over at least 15 min

**Antifungals**

QT interval prolongation may occur because of either a pharmacodynamic drug-drug interaction with other QT interval–prolonging drugs or a strong inhibition of CYP3A4 metabolism of the azole antifungal agents

Compared with posaconazole and voriconazole, fluconazole has less risk of inducing TdP

TdP = torsades de pointes.

---

**DRUG-NUTRIENT INTERACTIONS**

Drug-nutrient interactions can negatively affect the care of a critically ill patient. Critical care clinicians can prevent possible complications, improve patient outcomes, and decrease cost simply by recognizing the severity and relevance of potential drug-nutrient interactions or interactions of medications with alimentary tract access devices. Several factors must be considered when analyzing for drug-nutrient interactions. First, various nutritional elements may interact with the drug and render the agent inactive or with altered efficacy. Second, the location of the enteral feeding tube may affect the absorption of a given medication. Finally, the different medication formulations and release mechanisms available add to the complexity of drug administration through the available feeding tube.\(^8\)\(^9\)\(^5\) Table 46.13 describes several
common interactions between select medications and enteral nutrition and possible actions that may minimize this effect.

**Targeted Treatment Strategies to Minimize Drug-Nutrient Interactions**

The management of drug-nutrient interactions must be individualized according to the drug, the patient’s underlying medical conditions, the availability of alternative treatment options, and the feasibility of the intervention according to the clinical setting. The plan must be communicated with all health care providers involved in the care of the patient and may be subject to change, depending on the patient’s clinical response. If enteral nutrition is held for the administration of a medication, the rate of enteral feeds must be adjusted to maintain the same 24-hour volume and administered calories. In addition, the total volume of flushes needs to be monitored and considered when assessing fluid intake and volume status.

**EVALUATING THE PRESENCE OF DRUG INTERACTIONS AND DETERMINING THE CLINICAL SIGNIFICANCE**

There are few controlled DDI clinical studies, and significant variability is reported among individual cases.\textsuperscript{100-103} Databases such as Micromedex, LexiComp, Clinical Pharmacology, Facts and Comparisons eAnswers, and Drug Interactions: Analysis and Management can assist in identifying DDIs. However, each of these drug databases uses different approaches to identify and evaluate the same body of literature. For instance, Micromedex uses a 5-item rating scale (i.e., major, moderate, minor, none, and not specified) to classify the severity of DDIs.\textsuperscript{103} Drug Interactions: Analysis and Management uses a 5-item summary known as the ORCA (Operational Classification) system. The ORCA system is based on the severity of the interaction and the net benefit of administering the drug pair; ratings include avoid the combination, usually avoid the combination, minimize risk, no action needed, and no interaction.\textsuperscript{104} Sometimes little
agreement is found among these drug databases for what may be considered a serious and clinically relevant DDI. The overshadowing issue with these databases is that they are simply reporting DDIs that can occur.\textsuperscript{101-103} This is a reflection of DDIs that are included in the U.S. Food and Drug Administration–approved product labeling; classification of DDIs by therapeutic class rather than by individual agent and blanket inclusion of all drug formulations.\textsuperscript{102,103} From the prescriber’s perspective, if these drug databases are linked to a computer prescriber order entry system, too many alerts to fire may be caused that prescribers may consider clinically irrelevant and may result in alert fatigue and oversight of clinically significant alerts.

</table>
Because this has become a growing and recognized problem, an expert workgroup funded by the Agency for Healthcare Research and Quality has developed guidelines for the systemic appraisal of DDIs and recommended principles for including and presenting DDIs into clinical decision support systems. These guidelines define a clinically relevant DDI as one that is associated with either toxicity or loss of efficacy and that warrants the attention of health care professionals. The primary goal of the evidence workgroup in this consensus guideline is to identify the best approach for evaluating whether a DDI truly exists. It is acknowledged that the evidence supporting a DDI may be derived from case reports or retrospective reviews or extrapolated from in vitro studies and a few controlled clinical studies. A standard approach is recommended in these guidelines in order to evaluate case reports; thus, the Drug Interaction Probability Scale (DIPS) and the Drug Interaction Evidence Evaluation (DRIVE) instrument were created to be used for a given body of literature. The DIPS is a 10-item scale that was designed to assess the probability of a causal relationship between an event observed in a patient and a potential DDI. The total score is used to estimate the probability that the observed event is causally related to the medications. Probability is assigned as doubtful, possible, probable, or highly probable. The DRIVE instrument establishes the existence of a DDI through the following methods: uses simple evidence categories, includes causality assessment with DDI case reports (by DIPS), applies reasonable
extrapolation from the existing data, addresses evidence or statements provided in product labeling, and describes study quality criteria and interpretation in the context of DDIs.\textsuperscript{100} If the evidence of a DDI has been appropriately analyzed using the DIPS and DRIVE instruments, clinicians must then determine the clinical relevance. The factors to consider include the clinical consequences to the patient, the incidence at which the DDI occurs, any risk factors or mitigating factors that determine the susceptibility to the DDI, and an assessment of the seriousness of the DDI.\textsuperscript{100,102} This process seems methodologically sound; however, the DRIVE instrument must be formally evaluated and validated before used in the large drug databases previously discussed.

In addition, drugs that belong to the same pharmacologic class should be treated individually unless proven otherwise. Most class-based DDIs are pharmacodynamic in nature, whereas pharmacokinetic interactions can rarely be generalized and applied to all agents within a drug class.\textsuperscript{100,102} Even if the DDI was classified as a class effect, the magnitude of the effect may vary among each agent. A primary example of this point is that azoles have different potencies for the inhibition of the CYP3A4 enzyme. For instance, itraconazole causes a 27-fold increase in the AUC of triazolam, and fluconazole causes a 4.4-fold increase in the AUC of triazolam; both are clinically relevant, but the magnitudes are very different. Therefore, the evidence workgroup recommends that, in the absence of drug-specific data, a class-based interaction be reasonably assumed if the mechanism of interaction is consistent with the known pharmacology of one or both drug classes involved.\textsuperscript{100,102}

Additional work is needed to recognize, determine the significance of, and monitor clinically relevant DDIs. It is the responsibility of every clinician to be vigilant in identifying DDIs. Each member of the multidisciplinary team has a role in the prevention, identification, and resolution of DDIs in order to optimize patient care and ensure safe medication administration. Physicians should justify and review each drug regularly, screen for DDIs with each drug addition or deletion, and integrate the information that is discussed on multidisciplinary rounds.\textsuperscript{8}
Pharmacists should review each medication order for DDIs, assist in drug selection or substitution, and monitor for any adverse drug events. Nurses should assess and monitor drug administration and document any adverse drug events or change in patient status. The health system multidisciplinary team should work together to regularly reevaluate and update the list of DDIs identified within its clinical decision support system to remain current with the evolving scientific literature.

CONCLUSION

There are several factors to consider when identifying and determining the clinical significance of DDIs. Micromedex, LexiComp, Clinical Pharmacology, Facts and Comparisons eAnswers, and Drug Interactions: Analysis and Management can assist clinicians in identifying DDIs. The severity ratings may vary among these databases, and the clinical significance of the ratings used has not been fully established. The DDI alerting systems in every institution vary according to what is commonly observed as significant to that specific institution. Internal expert opinion and one of the mentioned drug information databases are commonly used to build an institution’s electronic DDI alerting system. Once an internal identification system has been determined, a clinician’s evaluation of an identified DDI should include understanding the mechanism and onset of the DDI, possible patient outcomes, and clinically appropriate alternative therapeutic options. This rationale and thought process may aid in the decision to either avoid or monitor a drug combination that is tailored to the pharmacotherapeutic need of an individual patient.

GCS  Glasgow Coma Scale
ICU  Intensive care unit
ISS  Injury Severity Score
MELD  Model for end-stage liver disease
MODS  Multiple Organ Dysfunction Score
INTRODUCTION

Many scoring systems are used in acute hospital settings and particularly in the critical care areas. Patients are admitted to intensive care units (ICUs) with a variety of primary diagnoses, and each patient presents with his or her own set of underlying conditions. Furthermore, the type and acuity of patients in a particular ICU is affected by the organization of the hospital, the patient population of that hospital or area, and the types of physicians and subspecialists that are available. Patient populations need to be defined by objective and clear criteria and not simply by the unit to which they are admitted. A “critically ill patient” could be defined in several ways according to these and more variables. Acute illness scoring systems try to provide specific, objective measurements that are reproducible in many ICU environments.

Objective and reproducible measures are particularly necessary if research and quality improvement projects are to be successfully completed and the results applied to similar populations. Selecting an appropriate scoring system can be one of the key elements of developing a successful project. Scoring systems are often used to develop or identify risk stratification for a given patient population. By dividing patient populations into various risk groups, a researcher can better compare like patients and apply appropriate statistical tests and comparisons. Quality improvement projects effectively use scoring
systems by selecting validated scoring systems that are commonly used by facilities with like patient populations. For example, if a particular ICU selects a scoring system that is not used by similar units or institutions with similar patient populations, that system will not allow for appropriate comparisons and may give data that are unreliable or may lead to projects that are not focused on the correct outcome.

In addition to research applications, clinicians are often faced with providing guidance to families or evaluating their own practices to help predict which patients will need continuing intensive care and which patients may benefit from lower acuity of care, or even withdrawal of care. Although most scoring systems are not intended for individual patient decision-making, they can help establish baseline statistics that can be used to better inform clinicians and families about the overall outcomes that may be expected given the available evidence. For all of these reasons, many types of acute illness scoring systems have been developed to provide consistency in the reporting and evaluation of patients with critical illness for a variety of disease states and predicted outcomes.

OVERVIEW OF ACUTE SCORING SYSTEMS

Most scoring systems are developed by collecting data on many patients and comparing the available data with the patients’ ultimate outcome. Two key elements in the evaluation and use of scoring systems are calibration and discrimination. Calibration evaluates the performance of a scoring system across patient populations, comparing the actual outcome with the predictive outcome. One of the more common statistical tests for assessing calibration is the Hosmer-Lemeshow test. Although this test provides better data as the size of the database increases, it should not be the sole test used to determine optimal test calibration for a particular patient population. Discrimination describes the ability of a model to accurately discriminate between patients who die and those who do not. Statistical tests such as the area under the receiver operating characteristic (ROC) curve describe discrimination of a particular
model. An ROC of 0.5 represents a purely chance association, and discrimination of a particular score improves as the ROC nears 1.0. Therefore, before using a given predictive scoring system in a quality improvement or research project, or before considering use in aiding a prognostic model for care decisions, the statistical reliability of the scoring system should be thoroughly investigated.

Scoring systems can be applicable to acutely ill patient populations in general or applicable only to specific disease states. Selecting the best scoring system for a research project or identifying the most appropriate criteria for optimizing patient care can be challenging for any critical care practitioner. The key elements are understanding the validated populations for a scoring system, selecting the appropriate data points for a particular disease state, and then correctly and consistently calculating scores. In the past several years, the proliferation of online and application-based calculators has made the data entry and calculation components relatively easy. However, selecting the correct data for entry often depends on having a clear understanding of the score, the applicable populations, and how to accurately select the appropriate data points for entry into the system. This chapter reviews many of the common scoring systems used in clinical practice, identifies the basic calculation approaches, and lists the primary patient populations and uses for each score.

**APACHE Score**

The Acute Physiology and Chronic Health Evaluation (APACHE; Cerner Corp., North Kansas City, MO) scoring system is one of the most well-known and commonly used scoring systems to assess severity of illness in critically ill patients. The APACHE system was first developed in the late 1970s/early 1980s and is currently in the fourth revision of the system, although the APACHE II and III versions of the score remain in common use within practice. Clinicians should be trained on how to accurately calculate and use the score specific to the version in order to optimize inter- and intrarater reliability. Preferably, the required data points are
automatically fed to the APACHE scoring system from the medical record to minimize variability, but manual data collection is also an option although usually much more time-consuming.\textsuperscript{3} The APACHE II score consists of three domains that include the Acute Physiology Score (APS), the Age score, and the Chronic Health Score.\textsuperscript{8} The APS component is determined by identifying the worst values recorded (high or low) within the previous 24 hours or within 24 hours of admission.\textsuperscript{16} Because values may change, it is important to note the application of the scoring system and the ways in which data were reported in a quality project or research design. Those values are then converted to a score that is summed. Values not available result in a score of zero for that element. A similar methodology is used for the III and IV versions.

Many versions of the APACHE scoring systems are available on the web. However, the APACHE III and IV systems have additional data points compared with APACHE II, and calculating the score without specific training and significant practice can lead to incorrect results and significant variability.\textsuperscript{13-15} By comparison, the APACHE II score is relatively easy to calculate by investigators or clinicians who lack full access to the APACHE IV data system. As with any scoring system, there is some intra- and interrater variation in calculating the scores with any of the APACHE versions, which can limit the usefulness of the score if strict attention to methodology is lacking.\textsuperscript{17}

Two elements of the APACHE score can be especially prone to introducing variability into the scoring system. One of the most difficult data elements to determine is the Glasgow Coma Scale (GCS) score in patients who are mechanically ventilated and sedated. The GCS measures basic neurological function on the basis of response to pain (1–6 points), verbal response (1–5 points), and eye-opening response (1–4 points), with total scores ranging from 3 to 15. To avoid false elevation of the APS score within the APACHE system, the pre-sedation GCS level should be recorded whenever possible. Medications and other therapies will likely affect the level of response of the patient and therefore the GCS.\textsuperscript{18} The Chronic Health Score component of the score is the second area that significantly affects
reliability of the system. Although this component is clearly defined when using most online calculators, it may not be easily described when homemade calculators or shortened versions of the scoring tool are used. Of note, multiple chronic conditions are not additive for this score because the patient can only receive a maximum of 5 points within the Chronic Health Score.

The current version of the APACHE (APACHE IV) scoring system provides the most accurate information regarding the predicted mortality of a patient population as well as the predicted length of stay.\textsuperscript{10,19} However, the APACHE II version still provides reasonable calibration and discrimination for some patient populations.\textsuperscript{20} As an investigator or quality project leader chooses a tool, the resources available will often drive which version of APACHE is selected.

Several websites offer online calculation of the score with good explanations of how to proceed. The version (II, III, or IV) being used should be noted because the appropriate collection and recording of data differ, depending on the version. Furthermore, online calculators often offer a calculated mortality rate or probability, but the rates determined by these systems may not be as accurate as the data that would be obtained with the APACHE IV system in full use and, in general, should not be used to predict mortality or outcome for specific individual patients.

The APACHE scoring system remains one of the most common tools for comparing the outcomes of a particular unit with those of peers as well as a common risk stratification tool for research studies that need to quantify severity of illness for their study population(s). Critical care clinicians should have a functional knowledge of this system and understand how the reported results may affect quality outcomes or identify appropriate patient populations for applying research results.

\textbf{SAPS Score}

The Simplified Acute Physiology Score (SAPS) was initially described in 1984 and was then revised in 1993 as the SAPS II.\textsuperscript{21,22} The SAPS II
score identifies 17 variables to provide a predicted mortality rate. The original study evaluated data within the first 24 hours of ICU admission; however, some calculators and investigators have used worst values in the past 24 hours to calculate the score. The mortality accuracy of the SAPS II score is somewhat questionable at this point because the data used to determine the mortality rates are now more than 20 years old. The SAPS 3 score was developed to address some of the inconsistencies with the SAPS II score, used patients from several regions of the world, and improves on the predictability of the score and simplifying data collection. The SAPS 3 score is an “admission score” because the data were collected within an hour before or after ICU admission. Furthermore, SAPS II and SAPS 3 were developed with data from patients in several countries as opposed to the APACHE system, which primarily used patients from the United States.

Mortality Probability Model

The mortality probability model (MPM) was originally developed in the 1980s, and the current revision (MPM0-III) has been in use since 2007. The MPM uses variables present on admission to the ICU such as comorbidities, acute diagnoses, and only three physiologic variables to provide mortality prediction. The current revision has a slightly lower level of discrimination than other models (e.g., APACHE). A further limitation of this model is that it does not work as well for patients with rapid changes within the first 24–48 hours of ICU admission because it only uses admission variables. However, the level of data collection is less with the MPM0-III model, and it does not require a diagnosis for use, so it may have advantages, depending on how data are collected within an EMR (electronic medical record).

SOFA Score

The Sequential Organ Failure Assessment (SOFA) score is calculated on the basis of the function of six organ systems (pulmonary,
Each organ system is scored on a 0–4 scale, and the SOFA has a maximum score of 24. In contrast to some of the other scoring tools, the SOFA score is intended to be tracked on a daily basis within the ICU, and the day-to-day change can be used as an objective measure to track the progress of an individual patient. Mortality rates have been correlated with both the peak SOFA score and the change in score from ICU admission. The SOFA score was also combined with the APACHE score to try to improve the prediction of mortality rates in at least one study. This score is particularly useful in research trials and quality projects where tracking and evaluating day-to-day progress of the patient is important to study outcome.

**MODS Score**

The Multiple Organ Dysfunction Score (MODS) is very similar to the SOFA score. Six organ systems are scored on a 0–4 scale with a maximum total score of 24. The main difference between the MODS and SOFA scores is the scoring of the cardiovascular system. The MODS approach uses a computation with the heart rate and blood pressures, whereas the SOFA score uses an approach of recording both blood pressure readings and whether vasopressor support is necessary. The MODS score was specifically described as an outcomes measurement in the original publication. However, a predictive component is available with associated mortality rates based on the calculated score and the number of ICU days for the patient. The MODS and SOFA scores have been compared in clinical practice and found to be similar in predicting and measuring outcomes.

**TISS Score**

Not all scoring systems are focused on patient mortality. For example, the Therapeutic Intervention Scoring System (TISS) can be used to measure and help determine staffing needs (particularly nursing) by...
measuring specific nursing activities. The score was initially developed in the 1970s, revised in the 1980s, and shortened to the TISS-28 score in the 1990s. The areas measured in the score include basic measures, cardiovascular support, ventilator support, renal support, neurological support, metabolic support, and specific interventions. The TISS and TISS-28 scores have also been used to measure certain outcomes and costs.

SCORING SYSTEMS IN SPECIFIC DISEASE STATES

Trauma

Several scores are used in measuring the severity of injury in trauma patients. Many of the common scores described previously in this chapter can be applied to trauma patients, but many scores have also been developed to be used specifically in trauma patients. Some scores do not require full knowledge of all injuries. In addition, several scores are based on the anatomic location and type of injury to calculate the full score. Trauma scores are used to provide triage assistance, to quantify injury patterns for registry database submission, or both. Three of the most common scores are described in the sections that follow.

ISS Score

The Injury Severity Score (ISS) has been used for more than 40 years to describe the initial injury in trauma patients. The score is calculated on the basis of the sum of squares of the three most injured body areas, with a score range of 1–75. The ISS can help predict mortality, allow for data comparison for quality improvement for a trauma program, and be part of data submission to trauma registries. As with other scores, online calculators are readily available, but calculated scores should not be used as a sole method to predict mortality for individual patients.

A revision to the ISS has also been published. The new ISS
provides improved mortality accuracy over the original score using the worst injuries regardless of body region.\textsuperscript{49,53} This better represents multiple injuries that may be more severe in one anatomic area.

**Revised Trauma Score**

The Revised Trauma Score is a calculation based on respiratory rate, systolic blood pressure, and the GCS.\textsuperscript{44,45} Each value is then coded to a score of 0–4. The coded score is then entered into a calculation to obtain to a final score that provides a mortality estimate that can be readily found with online calculators. Of note, this calculation more heavily weights the GCS to better represent the impact of head injury on overall survival.

**TRISS Score**

The Trauma Score and Injury Severity Score (TRISS) is a combination of the Revised Trauma Score and the ISS and incorporates the patient’s age.\textsuperscript{41} This score is used in several areas including many registry databases, trauma outcomes research, and internal quality improvement programs. The TRISS calculation provides a probability of survival, but as with any scoring system, this should be used cautiously for any individual patient decisions.

**Acute Kidney Injury**

**RIFLE Score**

The RIFLE acronym stands for risk, injury, failure, loss, and end-stage renal disease and is a system used to stratify acute kidney injury.\textsuperscript{54} The acute elements (risk, injury, and failure) are defined by a specific set of criteria listed in Table 47.1. Serum creatinine changes, glomerular filtration rate changes, and urine output concentrations are used to categorize the acute elements of the score. The use of urine output concentrations provides a more timely identification of kidney dysfunction than does the use of kidney injury definitions that rely solely
on laboratory values. Before the RIFLE system was developed, acute kidney injury was not consistently defined, and many studies have been completed in the past decade that evaluate the ability to predict outcome and stratify patients with acute kidney injury.\textsuperscript{55-61}

### Table 47.1 RIFLE Criteria for Acute Kidney Injury\textsuperscript{64}

<table>
<thead>
<tr>
<th>SCr Changes</th>
<th>Urine Output</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Risk</strong></td>
<td>1.5 × increase in SCr from baseline or decrease in GFR by ≥ 25%</td>
</tr>
<tr>
<td><strong>Injury</strong></td>
<td>2 × increase in SCr from baseline or decrease in GFR by ≥ 50%</td>
</tr>
<tr>
<td><strong>Failure</strong></td>
<td>3 × increase in SCr from baseline or a SCr of ≥ 4 mg/dL or decrease in GFR by ≥ 75%</td>
</tr>
<tr>
<td><strong>Loss</strong></td>
<td>Complete loss of kidney function for at least 4 weeks</td>
</tr>
<tr>
<td><strong>End-stage renal disease</strong></td>
<td>Complete loss of kidney function for &gt; 3 mo</td>
</tr>
</tbody>
</table>

GFR = glomerular filtration rate; SCr = serum creatinine.

The RIFLE system is one example of a scoring tool that can be used to describe either a patient population or individual patients. In describing a patient population for a research study, an investigator may use the RIFLE system to describe the number of patients who met each of the various criteria. However, the bedside clinician may use the RIFLE system to determine the degree of organ dysfunction for an individual patient.\textsuperscript{61} It is important to understand how a specific scoring tool is used in a particular context to understand the implications of the data that are presented.
AKIN Staging

The Acute Kidney Injury Network (AKIN) has suggested alterations to the RIFLE criteria by adjusting the changes in serum creatinine and urine output; this is described in Table 47.2.\textsuperscript{55,62} However, the AKIN score has not shown demonstrable advantage over the RIFLE criteria with respect to discrimination or calibration.\textsuperscript{55,57-59,63}

The RIFLE and AKIN criteria can be very important tools for the critical care pharmacist to remember and understand. Many medications used in the critically ill patient have the potential to induce damage to the kidney or are cleared by the kidneys and require dose adjustments with alteration in kidney function. Appropriate monitoring of both urine output and serum creatinine concentrations, using the RIFLE or AKIN criteria as a guide, is an important part of the overall patient care plan.

Although the RIFLE and AKIN criteria can be helpful in determining the degree of kidney injury or failure, they do not directly assist with medication dose adjustments. Typically, the Cockcroft-Gault equation is used for most medication dose adjustment. However, this equation was not developed with critically ill patients that have many changing variables in mind.\textsuperscript{64}

<table>
<thead>

</tr>
</tbody>
</table>

Table 47.2 Acute Kidney Injury Network Score\textsuperscript{62}

Pancreatitis
Pancreatitis can be a difficult disease state to accurately describe expected or predicted outcome because patients can become extremely ill very quickly. Therefore, several scoring systems have been developed through the years to describe objective measures and to accurately describe the likely outcomes of the disease process and assist in identifying patients in whom rapid aggressive care is most beneficial. The Ranson criteria are the oldest and most widely known set of criteria.\textsuperscript{65,66} However, in the 40+ years since these criteria were developed, other systems have been developed with increasing prognostic capabilities.\textsuperscript{67-70}

The Ranson criteria use 11 variables scored as either 0 or 1.\textsuperscript{65,66} Five of the variables (age, white blood cell count, glucose, aspartate aminotransferase, and lactate dehydrogenase) are scored at admission, and the remaining six are scored within 48 hours (serum calcium, change in hematocrit, hypoxemia, blood urea nitrogen [BUN] increase, base deficit, and fluid overload). The scoring breakpoints are different depending on whether the pancreatitis episode was caused by gallstones. Severe pancreatitis is defined by a score of 3 or greater. Although the Ranson criteria provide a reasonable predictive outcome, it takes a full 48 hours to complete the score and requires that specific laboratory variables be drawn within the specified period.

In contrast, the BISAP (Bedside Index of Severity in Acute Pancreatitis) is a simpler scoring system completed as soon as the variables are available after admission.\textsuperscript{67,69} These variables include a BUN concentration greater than 25 mg/dL, impaired mental status, SIRS (systemic inflammatory response syndrome), age older than 60, and pleural effusions. Each variable receives a score of 0 or 1, and the total score of greater than 3 describes severe acute pancreatitis. Each point scored is correlated with an increase in mortality. Compared with the Ranson criteria, the BISAP score performs at a similar specificity but somewhat lower sensitivity.\textsuperscript{67}

Scoring systems for pancreatitis severity have also been evaluated according to computed tomography (CT) results. Scores like the CT severity index (CTSI) and Balthazar grading system have been compared with clinical (non-radiographic) scoring systems, but with
similar predictive results.\textsuperscript{69,71}

The Atlanta classification (2012) is the standard consensus-driven tool for describing acute pancreatitis.\textsuperscript{68} This classification describes acute pancreatitis and mild, moderate, or severe acute pancreatitis on the basis of both CT findings and organ dysfunction described by the modified Marshall score. The modified Marshall score evaluates renal, respiratory, cardiovascular, hematologic, and neurological systems.

Ultimately, several clinical- and radiologic-based scoring systems for acute pancreatitis perform at similar levels of sensitivity and specificity. Beyond the specific scores for pancreatitis, APACHE and other general critical illness scores have utility in pancreatitis scoring.\textsuperscript{71,72} Some scores provide for mortality prognostication and resource use, whereas others serve to better describe patient populations for research purposes.

\textbf{Pneumonia}

Pneumonia scoring systems are not necessarily limited to ICU patients, but they are commonly used to describe the severity of illness of these patients in studies involving critically ill patients. Some of the most common pneumonia scores are the CURB-65 score and the Pneumonia Severity Index (PSI).\textsuperscript{73,74} The CURB-65 score is calculated by giving a point for each of the variables listed in Box 47.1.\textsuperscript{74} A score of 0 can likely be treated at home, whereas a score of 3 or more indicates a higher risk of death, and ICU admission should be considered particularly for a score of 4 or 5. The PSI uses a two-step process with a relatively simple yes/no algorithm to classify a patient into a low-risk score (category I) or into the higher-risk II–V scoring range.\textsuperscript{73} The higher-risk calculation then assigns points from a variety of symptoms and comorbidities from five categories: age, place of residence, physical examination findings, comorbid conditions, and radiologic and laboratory findings.

Clinical application of the CURB-65 score and the PSI may include use in some decision support tools or be used for predicting or directing location of care.\textsuperscript{75,76} The PSI has less discrimination for ICU
care, and the many data points make it difficult to use in a prospective manner unless data are automatically taken from the medical record.\textsuperscript{76} Although the CURB-65 score is fairly easy to calculate, it may underestimate the severity of illness in some patients, particularly older adult patients who are frail.\textsuperscript{76,77}

**Acute Liver Failure**

Acute liver failure is another common condition in critically ill patients and there are several scoring systems associated with the disease process.\textsuperscript{11,78-81} Patients appear very ill, and it is difficult to determine their prognosis and level of care. Furthermore, acute liver failure often occurs on top of underlying chronic liver failure. Therefore, scores such as the model for end-stage liver disease (MELD) score and the Child-Pugh score are commonly used, but they often show no greater predictive ability than the APACHE system or scores like the SOFA score.\textsuperscript{11,78,80}

**Box 47.1. CURB-65 Score\textsuperscript{74}**

<table>
<thead>
<tr>
<th>Condition</th>
</tr>
</thead>
<tbody>
<tr>
<td>New-onset Confusion</td>
</tr>
<tr>
<td>Urea &gt; 7 mmol/L</td>
</tr>
<tr>
<td>Respiratory rate &gt; 30 breaths/minute</td>
</tr>
<tr>
<td>Blood pressure &lt; 90 mm Hg systolic or &lt; 60 mm Hg diastolic</td>
</tr>
<tr>
<td>Age older than 65 years</td>
</tr>
</tbody>
</table>

The Child-Pugh score ranges from 5 to 15 and is calculated with a score of 1–3 in each of these five categories: ascites, encephalopathy, international normalized ratio (INR), albumin, and bilirubin. The score then indicates class A (5–6), B (7–9), or C (10–15) depending on the score range. The MELD score uses the INR, serum creatinine
concentration, and bilirubin concentrations as well as the cause of liver disease within an equation to provide a score and a predicted mortality rate.\textsuperscript{82} Mortality increases with every 10 points in the MELD score. Prognostic scores for hepatic disease are sometimes used to prioritize patients for certain procedures or transplant selection on the basis of overall probability of survival.

**SUMMARY**

Many scoring systems are available to evaluate critically ill patients. Some are disease-specific, whereas others are predictive simply on the basis of the presenting condition of the patient or the patient’s day-to-day progress. Some are a mix of disease-specific and physiologic values. Although scoring systems may at times be useful in predicting mortality and providing information to caregivers and families, most systems are primarily used to stratify patients for research purposes or to evaluate populations of patients to assist in quality improvement initiatives. With the advent of many mobile apps and decision support tools, many of these scores can be easily or even automatically calculated. An understanding of the use and application of such scoring systems is important for any clinician practicing in the ICU so that the most effective and accurate scoring system can be used appropriately and not misinterpreted or applied to patients or disease states for which that particular score was not intended. Pharmacists should be particularly aware of scoring systems that may affect the use of medications by accurately predicting patients or populations that are comparable with published literature. Furthermore, the interpretation of many studies of critically ill patients requires a knowledge of scoring systems so that patient populations can be matched appropriately.

LEARNING OBJECTIVES

1. Describe at least three ways that hospitals benefit from intensive care unit (ICU) pharmacy services.

2. Describe how a hospital’s strategic goals affect designing and implementing ICU pharmacy services.

3. List at least three factors that justify ICU pharmacy services.

4. Describe at least two ways that pharmacist clinical credentialing and privileging enhances ICU pharmacy services.

PGY2  Postgraduate year two
SCCM  Society of Critical Care Medicine
INTRODUCTION

Critical care medicine has grown from a small group of physicians participating in patient care rounds in surgical and medical intensive care units (ICUs) in the early 1980s to their integrated role on a high-technology multidisciplinary ICU team in 2015. The first published textbook chapter on critical care pharmacy services in 1981 notes only 12 physician training programs in critical care medicine, with about 500 physicians practicing the specialty with no board-certifying examination. In addition, the Society of Critical Care Medicine (SCCM) was only 10 years old at the chapter’s publication.1 The year 2015 marks the 45th year of SCCM, with almost 16,000 trained professionals engaged in the multidisciplinary critical care model.2

Pharmacy’s growth in the area of critical care is as exponential. The first residency training programs for ICU pharmacists were designed by a few pioneers and at several institutions. Of note, in 1981, the Ohio State University recruited and trained one of the nation’s first critical care residents; that same institution was selected in 1982 to conduct the first critical care fellowship program, sponsored by the American Society of Health-System Pharmacists (ASHP).3 Similar to critical care physicians, pharmacists will be offered a board-certifying examination for the first time in October 2015.4

The role of the pharmacist in the ICU is to provide a broad-based approach to medication use through a comprehensive pharmacy service. For example, a pharmacist attending ICU patient care rounds may be able to recommend an appropriate drug for a specific critical condition—but may be unable to provide timely drug delivery because of the lack of a pharmacy distribution area (e.g., a pharmacy satellite) in the immediate vicinity of the ICU. The service provided by the pharmacist is not comprehensive because the pharmacist is unable to provide the medication in a timely manner. Or furthermore, the ICU nurse caring directly for a patient may be burdened with the responsibility of compounding an intravenous medication because of a lack of pharmacy intravenous admixture preparation services.
Pharmacy-based services for preparing intravenous products have been shown to prevent errors and improve efficiencies; lacking this service in the ICU does not provide a comprehensive approach to care. The lack of comprehensive pharmacy services shown in these two scenarios may lead to inefficiencies, errors, or delays in treatment.

Today’s ICU requires a comprehensive pharmaceutical service that includes both operational and clinical services to meet its medication needs. A position statement published some 15 years ago by thought leaders in critical care pharmacy is still applicable today—that optimal critical care pharmacy services involve clinical cognitive pharmacists’ skills together with operational services such as a pharmacy satellite, preparation of intravenous admixtures, and an integrated electronic medical record supporting an automated medication administration record.\(^5\) \textbf{Table 48.1} lists the components of comprehensive ICU pharmaceutical services.

Critical care pharmacy specialists are uniquely positioned to provide comprehensive pharmacy services because of their cognitive skills and relationship with other members of the ICU team. However, establishing and maintaining operational services requires administrative skills not necessarily taught during postgraduate year two (PGY2) training. The administrative skills necessary to develop a comprehensive ICU pharmacy service such as pharmacy operations management, pharmacy practice model design, human resources management, and financial reporting are often not the focus of the training in residency or fellowship programs. Although ASHP’s educational outcomes, goals, and objectives for PGY2 training in critical care require the review and evaluation of leadership and practice management skills, the degree to which they are covered is often variable and dependent on the pharmacy’s organizational structure and residency resources.

The following case exemplifies how an ICU pharmacist uses leadership and management skills to be an effective ICU practitioner. Recently, an academic medical center reviewed the drug costs associated with patients on mechanical ventilation greater than 96 hours. The costs were so much outside the range compared with those
of peers that the only suggested way to reduce expense was to significantly reduce the medication inventory or people. That review showed cost opportunities in the areas of extracorporeal membrane oxygenation (ECMO) therapy. The pharmacist reviewed the patient cases and combined his clinical knowledge of ECMO and appropriate medication use to the institution’s data. The ICU pharmacist then sorted the costs by various patient characteristics and developed a Pareto analysis for the senior management on the distribution of medication expenses in ECMO. The ICU pharmacist developed a presentation and executive summary for the chief of thoracic surgery, together with a plan for implementing a Plan-Do-Check-Act approach to decreasing costs. After 12 months, the medication costs for patients on ECMO were normalized to the 50th percentile for the compare group, preventing any other drastic reductions in staff or services for these patients. Without knowledge of some basic leadership and management skills, the ICU pharmacist would have been unable to effectively address a clinical problem that increased an organization’s use of resources.

This chapter provides a primer to the critical care pharmacy specialist on leading and managing ICU pharmacy services. Specifically, this chapter describes the elements of a comprehensive ICU pharmacy service and its impact on a hospital organization, together with the skills necessary to lead and manage an ICU pharmacy service. This chapter also discusses the future role of pharmacists in the ICU and the impact of new technology on ICU pharmacy services. A large retrospective study showed that increased pharmacist staffing positively affects hospital mortality rates; however, the pharmacy services coverage is not consistent across hospitals. As a result, every critical care specialist must now possess skills that focus not only on the clinical care of ICU patients, but also on the business and leadership acumen to develop an effective role for the critical care pharmacist in the interdisciplinary ICU model. With a focus on skills in practice leadership and management, together with clinical skills, critical care pharmacy services will continue to grow in this country.

---

### ICU PHARMACY SERVICES AND THE HOSPITAL

Comprehensive pharmaceutical services for ICU patients are based on the significant medication needs of these patients. In most ICUs, patients are admitted because of their need for intensive, one-on-one nursing care and the focused attention of the medical staff. Intensive care unit patients have multisystem and multiorgan failure, requiring
very specific pharmacotherapy to manage these issues. The ICU pharmacy service also promotes quality and safety in health care by reducing the risk of adverse drug events and medication errors (MEs).

**Medication Needs of ICU Patients**

Intensive care unit patients require more medications than do non-ICU patients. An informal observational study in a university hospital showed that the ICU patient had on average 26 different medication orders, compared with 11 for the non-ICU patient. A large percentage (greater than 65%) of these medications are for intravenous formulations; ICU patients’ ability to take oral medication may be compromised by their inability to swallow or because edema of the gastrointestinal (GI) tract limits drug absorption. In addition, ICU patients may require the use of tubes or catheters to access the GI tract, requiring that medications be available in the oral formulation or compounded as an oral liquid.

Intravenous medications are the primary dosage formulation administered to ICU patients—and many require extemporaneous compounding by hospital staff. Compounding of intravenous medications is most appropriately done under the proper conditions as required by the United States Pharmacopeia (USP). The USP sets the standards for drug product formulation and testing; USP chapter <797> details the requirements for the safe compounding of intravenous medications for both immediate use and batch preparation. Most regulatory agencies, including the Joint Commission, state boards of pharmacy, and health departments, require hospitals to comply with USP guidelines for preparing intravenous admixtures.

A significant medication need of patients is the timely delivery of medications in urgent and emergent situations. Some hospitals use satellite pharmacy spaces in the ICU to place the pharmacy staff and the medication dispensing equipment closer to the patients, reducing the logistics of medication delivery from a central pharmacy area. Many pharmacy departments are located in the basement of a hospital, and often, pneumatic tube carrier systems are unavailable. As
a result, delivering medication may require a technician to hand deliver the medication, using elevators, steps, and walkways to reach the ICU. Locating a pharmacy satellite area in or around the ICU eliminates these delivery issues and makes the medication available in a timely manner. The joint statement from SCCM and the American College of Clinical Pharmacy (ACCP) on critical care pharmacy services lists a satellite pharmacy with 24-hour, 7-day/week services as an optimal provision of pharmaceutical care services.\textsuperscript{8}

**Medication Costs and Quality in the ICU**

The costs of medications for ICU patients exceed those for non-ICU patients. In a study of almost 23,000 ICU patients, researchers showed that ICU drug costs accounted for almost 38% of total drug costs and increased at a rate much greater than for non-ICU drug expenses.\textsuperscript{9} Furthermore, pharmacy charges ranked as the fourth highest charge in an organization. These data emphasized the differences in the costs of ICU pharmacotherapy and the importance of developing evidence-based practices for drug use and disease state management in the ICU together with multidisciplinary collaborations.

Patients treated in an ICU have multiorgan failure, leading to a significant risk of adverse drug reactions and MEs because of the organ toxicity of antibiotics, intravenous medications, and anticoagulant and antiarrhythmic drugs. In addition to complex drug therapy and the rapidly changing condition of ICU patients, the environment may be chaotic and confusing, leading to errors caused by communication issues. Other factors include complex drug administration requirements and altered pharmacokinetics. The incidence of ICU MEs in general has been documented at a median value of 106 per 1,000 patient-days, or around 10%.\textsuperscript{10} The severity of MEs in the ICU exceeds that in the non-ICU. The harm caused by an ME is usually an injury related to events such as hypotension from mistaken overdoses of medication, organ damage from overdosages of medication, and cardiac arrhythmias from rapid administration of cardiac medications. Because MEs have a greater incidence of harm, vigilance in monitoring patients...
LEADERSHIP SKILLS REQUIRED IN LEADING AND MANAGING ICU PHARMACY SERVICES

This chapter has reviewed important aspects of the impact of the comprehensive pharmaceutical service on the medication needs of ICU patients. Implementing ICU pharmaceutical services requires a broad knowledge of operational and clinical pharmacy services, specifically focused on the needs of ICU patients. This next section of the chapter discusses in some detail the important skills necessary to lead and manage ICU pharmacy services. These skills focus on basic leadership skills such as developing strategic planning, justifying pharmacy services, providing operational and clinical services management, managing personnel, and using alternative pharmacy practice models. In addition, resources for gaining these skills will be presented so that pharmacists can gain the necessary knowledge in a non-traditional manner (e.g., web resources, conference, home study programs).

These leadership skills are also important for managing the relationships that the ICU pharmacist may have with the network of individuals who coordinate the care of ICU patients (Figure 48.1). For example, interactions with several members of this network require variable leadership and management skills. Moreover, the pharmacy administrator requires the ICU pharmacist to be a clinical expert but also to have the ability to effectively plan for service growth and deal effectively with physician relationships. The nursing leadership of the ICU requires the ICU pharmacist to understand how nursing workflow and priorities intersect with pharmacy operations, resolving any issues that may interfere with those priorities.

Strategic Planning

Strategic planning is the skill of developing a work plan for a clinical service that is consistent with the strategic needs of an organization. The ICU pharmacy service consistently meets the strategic plan of any
hospital organization by addressing the specific impact of the pharmacy service previously discussed. Many organizations fail in their strategic plan because of a very simple shortfall—the plans are too detailed and complex. Simple plans are much more effective because it is easier for staff to remember and understand their applicability to the organization. A simple strategic planning framework focuses on three key elements: analysis, planning groups, and execution. These three areas, if given the proper attention, will result in an effective strategic plan for the ICU pharmacy service. Intensive care unit pharmacists must be involved in establishing the pharmacy’s plan for this area because their understanding of patient needs and how pharmacy meets patient needs is central to any strategic plan for an ICU. Because strategic planning is not often taught in training, excellent resources are available. In particular, the National Council of Nonprofits offers an excellent guide for strategic planning.\(^\text{12}\) An analysis of the ICU pharmacy service is usually conducted through interviews with key stakeholders, as well as examining essential ICU data on medication cost, quality, and safety metrics and staff and patient satisfaction. The stakeholders should include physicians, nurses, administrators, and patients. The interviews assess the stakeholders’ thoughts on the strengths and weaknesses of the ICU pharmacy program and thoughts on the department’s future directions. Additional analyses involve conducting a SWOT (strength, weakness, opportunity, and threat) analysis of the pharmacy services and surveying the pharmacy staff on their thoughts for future directions of the pharmacy service. The result of the analysis establishes strategic priorities and tactics for the ICU pharmacy services, examples of which are listed in Table 48.2 and Table 48.3. These priorities must match directly and contribute to the organization’s goals.

The planning groups on the ICU pharmacy services address the priorities developed from the strategic planning process. For example, enhancing the ICU pharmacy practice model requires establishing a planning group that will develop guiding principles, conduct an assessment of the strengths and weaknesses of the model, and recommend a plan for practice model changes. Other planning groups
may include an employee satisfaction group and a research focus group. Through these planning groups, tactics can be developed to increase the ICU pharmacy service’s growth. A tactic is a careful action or plan to achieve a specific end.

**Figure 48.1** Clinical care network of the ICU pharmacy.

</tr>
</tbody>
</table>
The most important aspect of a successful strategic plan for a comprehensive ICU pharmacy service is executing the tactics design to meet the strategic plan. Successful execution requires skill in communication and project management. Most strategic plans are designed as a sophisticated “to-do” list that outlines the tactics together with a time-line and the responsible individual for implementing those tactics. Meaningful metrics for the success of an ICU pharmacy service strategic plan include, but are not limited to, patient satisfaction scores, clinical productivity, harmful MEs, order processing times, readmission rates, staff satisfaction, and financial performance (cost of drugs adjusted for patient acuity). A strategic plan is a fundamental and required tool for pharmacy departments that want to improve their overall performance. A good plan involves having an effective analysis, establishing venues for employee input, and executing and tracking its progress. Patient-centered services for the ICU pharmacy can only be successful through a well-done and well-executed strategic plan.
The role of the ICU pharmacist in strategic planning is shown by the following example. A pharmacy director of a 300-bed hospital is moving the central pharmacy to another area of the hospital—far away from the ICU, which was previously serviced by the central pharmacy. As a result, the pharmacy director places developing an ICU pharmacy satellite as a key strategy in the department’s goals, tasking the ICU pharmacy to develop the strategic plan for the pharmacy design and operation. The ICU pharmacist surveys stakeholders to determine the needs of the pharmacy satellite, establishes an inventory to meet the clinical needs of the patients, and designs the appropriate staffing. Finally, the ICU pharmacist supervises the execution of the construction and opening plans for the pharmacy.

**Justifying ICU Pharmacy Services**

The strategic plan sets the framework for establishing a comprehensive pharmaceutical service; often, the plan requires a justification through the administrative structure in a hospital organization. Justifying a new service or an expansion of an existing service requires a combination of information based on published literature and institutional data.

**Institutional-Specific Data**

There are very specific institutional data that are important to justifying pharmacy services. These data include staffing ratios for nurses and physicians, medication costs for ICU patients, reported harmful MEs, length of stay, readmission information, mortality, and patient and family satisfaction.

Most institutions require that the pharmacy department submit a return on investment (ROI) for new programs; this requirement would be no different if the pharmacy department were justifying a comprehensive pharmacy service. An ROI is the benefit to the investor resulting from an investment of some resource. A high ROI means that the investment gains compare favorably with investment cost. As a performance measure, the ROI is used to evaluate the efficiency of an
investment or to compare the efficiency of many different investments. The ROI for a pharmacy service is calculated by determining the costs of the ICU pharmacy service (facilities/space, people, inventory) compared with the benefits of the service. The benefits of the service may be measured by cost savings or avoidable hospital deaths. Pharmacy-specific services that contribute to avoided hospital deaths that can be used in the ICU by pharmacists include managing policies and protocols, providing informal educational services, conducting medication use evaluations, attending medical rounds, conducting medication histories, managing adverse drug events, and responding to resuscitation events.

Published Data

Table 48.4 includes the fundamental, desirable, and optimal critical care pharmacy services. A 2013 report describes the role of the pharmacist as a member of the multidisciplinary team, including very specific clinical activities. The cost implications and potential adverse events prevented by the interventions of a critical care pharmacist were studied in an academic medical center. Interventions for an almost 5-month period were analyzed in a retrospective manner, with almost 85% of the interventions determined to have prevented a potentially serious adverse event. The total cost impact of the pharmacist interventions annualized to around $600,000–$850,000 in cost avoidance.

Another study shows the role of the critical care pharmacist in identifying significant drug-drug interactions. A prospective study showed that pharmacist involvement in a profile (medication regimen) review significantly reduced the incidence of drug-drug interactions compared with the control period (no pharmacist review of the medication regimen). Finally, pharmacists and physicians were surveyed on the perception of their impact on the clinical and financial impact of pharmacy services in the ICU. Critical care pharmacy services were perceived to have beneficial clinical and financial outcomes—specifically, the services considered fundamental by SCCM and ACCP. The study also showed strong support for the funding of
critical care pharmacy services and reimbursement for pharmacists practicing in the ICU.\textsuperscript{17}

**Operational and Clinical Services Management**

Managing operational and clinical services requires knowledge of several areas. The clinical services coverage requires planning to ensure that pharmacists are available to participate in patient care activities. For example, understanding the clinical rounding scheduled of the team is critical—and pharmacists should be scheduled appropriately to participate in those rounds. Documenting and measuring clinical workload is a critical skill that establishes the appropriate time standards for various clinical activities. These standards should be used to develop the required number of hours for providing clinical services.

Managing operations also requires knowledge of Lean Six Sigma (Lean), a methodology that relies on a collaborative team effort to improve performance in the ICU pharmacy area (usually a satellite pharmacy, central pharmacy service, or infusion service) by systematically removing waste to include expired medications, errors, overproduction, and inventory.\textsuperscript{18} The elements of Lean include designing a process such that the defect-free rate is 99.99966%, or six sigma.

• Disseminate results of clinical research, outcome, and administrative research, or laboratory analyses |
| Administrative activities | • Document services provided to the ICU  
• Serve on ICU and pharmacy committees  
• Monitor and report adverse drug events to hospital committee  
• Conduct medication use evaluations | • Attach economic impact to services provided by the ICU  
• Develop and implement ICU policies and protocols | • Design new pharmacy programs for the ICU |

IV = intravenous.

An important aspect of operational and clinical services management is the ability to understand and use institutional data. Specifically, these data include staffing ratios for nurses and physicians, medication costs for ICU patients, reported harmful MEs, length of stay, readmission information, mortality, and patient and family satisfaction. For example, the ICU pharmacy service would use statistics on patient volume to appropriately provide staffing to the ICU pharmacy; drug expense data can be used to focus interventions to include appropriateness or cost-savings projects.

Pharmacoeconomic Analytical Skills
The role of pharmacoeconomics in the ICU is important because ICU medications may be costly, but using these costly medications may be cost-effective in the treatment of a given ICU patient. The ICU pharmacist should understand the basic pharmacoeconomic terms and how to apply various analyses to drug use in the ICU. This is also important because many therapies in the ICU often lack the appropriate level of graded medical evidence. Table 48.5 lists the type of economic analyses and some examples in ICU patients. 19

Personnel Management
People are the most valued asset in health care; organizations are successful if they have engaged satisfied and passionate employees. In addition, employees expect to be supervised and managed in a way that provides them with job satisfaction and upward career mobility. It is important that the critical care specialist have the skills to manage both professional and technical personnel to include developing clear job descriptions, tracking performance management, and providing effective feedback on performance. Intensive care unit pharmacists are being selected for jobs that are located in a pharmacy satellite—with responsibilities to help in managing pharmacists and technicians. This management requires providing feedback to staff on issues around
clinical practice. In particular, the ICU pharmacist may also provide feedback to nursing staff on practice issues such as methods for administering and monitoring medications. There are several reasons to create clear job descriptions for the ICU pharmacy service; in general, job descriptions provide clear performance expectations, help with recruiting and hiring, and differentiate between various jobs within the pharmacy department. Job descriptions include the following: (1) the job or position title (and job code number, if applicable); (2) the reporting structure for the position; (3) a brief summary (one to three sentences) of the position and its overarching responsibility, function, or role within the organization and how it interrelates to other functions within the organization; (4) a list of the position's essential or key job duties; (5) the qualifications for the position (the specific knowledge, skills, employment, or other experiences, training, language, or aptitudes required for the job); (6) the educational requirements for the job, if any, such as degrees and licensing; and (7) the qualities or attributes that contribute to superior performance in the position. A well-written job description is a necessary component of effective personnel management because this document provides clarity on role function and performance expectations.

Clinical Privileging of ICU Pharmacists

In May 2012, the Centers for Medicare & Medicaid Services (CMS) modified its definition of medical staff to include non-physician practitioners. Pharmacists practicing in the ICU are an example of non-physicians who can now be classified as part of the medical staff, which creates an opportunity to privilege pharmacists if state and federal regulations are observed. Institutional clinical pharmacists are still unable to bill for their patient care services, but this change in CMS policy provides additional strategies for pharmacists to generate revenue for clinical services.

Privileging Basics

Privileging is the process by which a health care organization authorizes an individual to perform a particular clinical service within a defined scope of practice. Privileging is integral to the ability of physicians and mid-level practitioners (e.g., nurse practitioners, physician assistants) to provide independent clinical activities in a hospital or clinic. Privileging should not be confused with credentialing. Credentialing is the process by which an organization reviews and verifies an individual’s credentials to ensure that they meet established standards. A brief case shows the differences between credentialing and privileging. A hospital’s cardiac surgery department may require that physicians have the credentials of a medical degree, a state license, and specific residency training in interventional cardiology. That same hospital may only privilege specific physicians’ valve replacements depending on the credentialed physician’s specific case experience and outcomes.

For pharmacists, credentialing has been limited to verification by the health-system human resources department that pharmacists are graduates of an accredited school or college of pharmacy and that their license is in good standing. As an example, for a pharmacy department to credential and privilege pharmacists for administering immunizations, a pharmacist license as a credential and completion of a certificate program may be required. In addition, the department may require some competency assessment/review of knowledge on immunization indications, dosage, injection technique, and patient monitoring techniques.

Privileging pharmacists for ICU pharmacy activities can be a complicated process, and the pharmacy director must understand the basic steps of privileging and be able to apply them to privileging of the pharmacy staff. Because privileging is conducted by a hospital’s medical staff, gaining the support of ICU physicians to privilege pharmacists is a key initial step in the process. The director of pharmacy must develop a strategy that shows the benefits and values of privileging pharmacists for medication-related clinical activities.

Once the pharmacy gains support for pharmacist privileging in the
ICU, the necessary credentials for practicing pharmacists, specific scope of patient care service in the ICU, and initial and ongoing monitoring of quality performance in the patient care service must be determined. Although no official standards specify the credentials necessary for ICU pharmacists to become privileged, minimum requirements may include a pharmacy degree and a license to practice pharmacy. Expanded requirements can include residency training, board certification, number of years in practice, and level of specialization and competency examinations. As part of the privileging process, individuals will also need to undergo initial and ongoing quality monitoring. The institution must establish policies regarding which specific elements related to competency will need to be reviewed for ongoing evaluation and the frequency with which these reviews will need to occur. The scope of practice delineates the boundaries within which the pharmacist can provide clinical services and may differ depending on state pharmacy and medical laws and the bylaws of an organization’s medical staff. Independent activities where pharmacists can be privileged in the ICU may include the following: anticoagulation management; medication reconciliation (adjusting medication on discharge or transfer from the ICU); modification of drug regimens according to a patient’s renal, hepatic, and hematologic parameters; management of total parenteral nutrition therapy; conversion of intravenous medication to equivalent oral dosages; initiation of culture-directed antimicrobial therapy; Clostridium difficile management; and ventilator-associated prophylaxis management. Table 48.6 describes the specific activities involved with some privileges for ICU pharmacists.

### Privileging Activities

Within each of these various clinical activities, specific procedures or tasks that fall within the scope of practice must be specified. For example, for pharmacists who are privileged to manage anticoagulation, specific procedures include selecting the medication and the proper dosage and frequency, ordering appropriate laboratories, and selecting the appropriate consultative help (e.g.,
dietitian consult to prevent food and drug interactions). The pharmacy department must also develop an internal process to approve pharmacists to be privileged for a specific ICU patient care service. This involves defining appropriate performance measures for specific clinical privileges.

The United Kingdom Clinical Pharmacy Association established a critical care group that designed a process for credentialing advanced-level practice in critical care; this framework may serve as a guide for the growth of critical care privileging in U.S. hospitals.\textsuperscript{22} The group proposed a multipronged glossary of assessment tools for critical care proficiency: practice portfolio, case-based discussion, mini-clinical evaluations, and a 360-degree peer assessment. The practice portfolio contained documents to validate the experience of a practitioner in a specific area. Of importance, the portfolio should contain data to support the ACLF (advanced to consultant level framework), which is a UK-recognized framework describing the level of competency in pharmacy practice. Case-based discussions are designed to assess clinical decision-making and a candidate’s ability to apply knowledge to resolving the issues presented in the patient case. The mini-clinical evaluation exercise is based on the American Board of Internal Medicine approach, and it involves a group discussion with candidates on a specific case, with a series of predetermined questions about the case. Finally, the 360-degree assessment seeks input from all practitioners who work with the pharmacist in the clinical arena; usually, the evaluators are members of the team in which the pharmacist is a member. This framework may serve as a guide to a comprehensive evaluation of the skills needed to determine the competency of a pharmacist independently practicing in an ICU as a member of a multidisciplinary team.\textsuperscript{23}

**Privileging Benefits**

Privileging of pharmacists in the ICU has a variety of benefits. It improves the efficiency of pharmacists and physicians by avoiding the need for direct physician oversight of pharmacist activities. For example, pharmacists may modify a drug dosage for a patient and
enter a verbal order change in the electronic medical record with a physician co-signature. Given the time to identify and sign verbal orders in an electronic system, eliminating this activity by privileging pharmacists to independently perform the activity allows physicians to increase their ability to care for more patients, increasing the organization’s clinical revenue. Pharmacists also can more effectively use their time optimizing drug therapy and addressing medication-related problems without being limited by the availability of a physician.

CONCLUSION

Pharmacy services in the ICU are of great benefit to patients; in particular, comprehensive pharmacy services that use clinical and operational services to patients are the optimal pharmacy practice model. To establish comprehensive services, pharmacists must use both clinical and leadership skills. This chapter reviewed the leadership and management skills necessary for pharmacists to implement comprehensive ICU pharmacy services. Most pharmacists participating in PGY2 critical care pharmacy specialty training programs or pharmacists who have obtained their ICU pharmacy skills “on the job” have very little training in leadership and management. Lack of these skills may be a barrier to developing a comprehensive ICU pharmacy service.

Adapted from: The Ohio State University Wexner Medical Center Credentialing and Privileging Program for Pharmacists.
Resources are available for pharmacists to develop their leadership and management skills. The ASHP Foundation’s Center for Health-System Pharmacy Leadership, through the Leadership Resource Center (LRC), provides tools and opportunities for a variety of ICU practitioners who are experienced, emerging, or aspiring leaders. The LRC can provide teachings for those learning new skills or those honing existing leadership skills with the ultimate goal of enhancing their leadership knowledge and personal development. The LRC offers a Leadership Primer that provides foundational concepts for leading in a complex health care environment. A Leadership Self-Assessment also offers personal insights into individual strengths and development opportunities. In addition, a Leader’s Tool Kit offers awareness, user tips, and access to worksheets for useful leadership tools that can be used in the ICU. Finally, the LRC’s Focused Learning Modules offer in-depth self-study opportunities on key leadership topics, including (1) leading for influence and advocacy, (2) clinical microsystems: transformational framework for lean thinking, and (3) transformational change. Now, more than ever, the critical care specialist must possess skills that focus not only on the clinical care of ICU patients, but also on the business and leadership acumen needed to develop an effective role for the critical care pharmacist in the interdisciplinary ICU model. With a focus on the skills needed in practice leadership and management, together with clinical skills, critical care pharmacy services will continue to grow in this country.

Chapter 49  Medication Safety and Active Surveillance

Sandra L. Kane-Gill, Pharm.D., M.Sc., FCCP, FCCM; and Mitchell S. Buckley, Pharm.D., FCCP, FASHP, FCCM, BCPS

LEARNING OBJECTIVES

1. State the incidence of medication errors (MEs) and adverse drug events (ADEs).
2. Discuss the relationship between MEs and ADEs.
3. Explain why the critically ill population is at greater risk of MEs and ADEs.
4. Describe the retrospective and prospective methods of ADE detection in a medication safety surveillance system.
5. Consider surveillance strategies that can be used to prevent ADEs.
6. State how to measure an effective surveillance system.

INTRODUCTION

Medication errors (MEs) and adverse drug events (ADEs) remain a significant concern in the critically ill population. Several factors have been identified in the intensive care unit (ICU) population as increasing the risk of experiencing a ME or ADE. Medication errors are concerning because they can result in ADEs. Unfortunately, ADEs have been associated with deleterious outcomes including an increased risk of hospitalization, costs, and mortality. Medication errors and ADEs can occur at any stage within the medication use process (prescribing, transcription, dispensing, and administration) with preventative strategies targeting each of these phases. A multifaceted approach involving both, prospective and retrospective, medication surveillance systems can detect events for systematic improvements, mitigate ADE progression and reduce preventable ADEs.

MEDICATION SAFETY

Terminology

Medication errors and ADEs are terms often used in medication safety (Table 49.1). The National Coordinating Council for Medication Error Reporting and Prevention defines an ME as a preventable incident resulting in inappropriate drug use while the medication is in the control of the health care professional, patient, or consumer. Medication errors may occur at any step in the medication use process regardless
of whether patient harm occurred.\textsuperscript{4,5} An ADE is an injury experienced by the patient as a direct result of medication use, but it is not necessarily the result of an ME.\textsuperscript{4}

Confusion in the literature arises for ADEs because clinicians and researchers are not decisive with their definition of injury. Injury should be explained by the occurrence of end-organ damage, so an episode of asymptomatic drug-induced hyperkalemia (no end-organ damage) is not classified as an ADE, and an episode of drug-induced hyperkalemia that results in an arrhythmia (end-organ damage) is considered an ADE.\textsuperscript{2} The elevated potassium concentration caused by a drug is considered a drug-related hazardous condition (DRHC) because high potassium concentrations from drugs are an antecedent to injury and the opportunity for a pharmacist to intervene, thus preventing injury—in this case, an arrhythmia.\textsuperscript{2,5,6} The idea of an intermediate step or a DRHC, before an ADE occurs, can be applied to physiologic parameters as well as to laboratory values. This is shown in drug-induced hypotension that has not yet resulted in end-organ damage (i.e., acute kidney injury [AKI] or a myocardial infarction).\textsuperscript{6}

Adverse events can be classified as “preventable” or “non-preventable” as well as “potential.”\textsuperscript{1,5} An ME occurring with no patient injury is simply an ME. An ME that results in injury is a preventable ADE. The occurrence of an ADE without an ME is a non-preventable ADE. Non-preventable ADEs are more common than preventable ADEs.\textsuperscript{1,5,7} An ME that has the opportunity for injury is defined as a “potential ADE.” The classic example is a patient with a penicillin allergy who receives a penicillin antibiotic but has no reaction; thus, there is the potential for injury, but none has occurred. Potential ADEs may be intercepted.

The inconsistency surrounding the definition of an ADE versus that of an adverse drug reaction (ADR) is challenging to interpret, making comparisons between studies difficult. For some clinicians, a non-preventable ADE is considered synonymous with an ADR.\textsuperscript{1,5} For others, an ADR is thought to be any unexpected, unintended, undesired, or excessive response that requires medical attention.\textsuperscript{6,8,9} The relationship among these various terms is shown in Figure 49.1.\textsuperscript{2}

ADE = adverse drug event; ME = medication error.
Epidemiology of MEs and ADEs in the ICU

Medical errors and adverse events remain unacceptably high in the ICU, with drug therapy as one of the main causes.\textsuperscript{7,10-12} Medication errors occur more commonly than ADEs. The reported rate of MEs in the critically ill population is highly variable, ranging from 1.2 to 947 events for every 1,000 patient-days, with a median rate of 105.9 errors for every 1,000 patient-days.\textsuperscript{13} Differences in definitions, detection techniques, and specific ICU populations observed explain the wide variance in reported ME rates.\textsuperscript{13} Medication errors are of concern because of the possibility of resultant injury, known as a preventable
The incidence of ADEs is about 2-fold higher in the ICU population than in the general ward population (19 vs. 10 events, respectively, for every 1,000 patient-days). However, the rate of ADEs is no different after adjusting for the number of medications. Adverse drug event rates in the ICU have been reported to occur in about one-third of patients at a rate as high 87.5 events for every 1,000 patient-days.

The severity of ADEs is greater in the ICU than in the general ward. Cullen et al. found a higher rate of “life-threatening” consequences of ADEs in ICU patients than in non-ICU patients (26% vs. 11%, p<0.001). No significant differences in the severity between medical and surgical ICUs were found. Other studies have corroborated these findings, reporting that the overall greater harm occurs in the ICU than in the general ward populations (odds ratio [OR] 1.89, 1.62–2.17). Medication errors resulting in ADEs causing permanent harm (OR 2.45, 1.17–5.13), requiring life-sustaining intervention (OR 2.91, 1.86–4.56), or causing death (OR 2.48, 1.18–5.19) were more likely to occur in the critically ill population. Kane-Gill et al. found that a higher rate of MEs in the ICU than in the general ward resulted in temporary harm requiring intervention (10% vs. 4.4%) and interventions necessary to sustain life (1.7% vs. 0.8%).

Prolonged hospitalization, increased patient morbidity, and an increased risk of mortality are negative consequences of ADE occurrences. Adverse drug events result in prolonged hospitalization more commonly in critically ill patients than in general ward patients. An average difference of 20 days was seen for patients who had an ADE in the ICU compared with patients who had an ADE in the general ward (37.5 vs. 17.3 days, respectively; p<0.001). For patients in the ICU who had an ADE compared with those who did not, the hospital length of stay increased by 1.5–2 times, a finding that was consistent for medical and surgical ICU patients. In addition, the ICU length of stay incrementally increased with the number of ADEs experienced by the patient. In one report, the length of stay in the ICU for critically ill patients experiencing an ADE increased by about 3.5 days, and in another report, the length of stay increased by 2.38 days for every
ADE. One meta-analysis found that the ICU length of stay for subjects with an ADE increased by 6.7 days compared with subjects without any ADEs. Although the costs associated with ADEs specifically in the ICU are unknown, the estimated economic impact is substantial. One study evaluating ADEs associated with only intravenous medications in ICU patients at an academic hospital found an increased cost of $6,647. Furthermore, total hospital expenditures after an ADE in the ICU compared with expenditures in the non-ICU have been shown to be similar ($36,204 vs. $26,391, respectively, p=0.22). The crude mortality rate is significantly higher in hospitalized patients with an ADE than in hospitalized patients without an ADE (3.5% vs. 1.1%, p<0.001, respectively). Fortunately, the risk of death attributed to MEs in ICU patients is reported to be less than 5%.

**Systems Analysis of ADEs in the ICU**

The medication use process system has been divided into several nodes, including the ordering, transcribing/documenting, distributing, administering, and monitoring phases. Implementing safe medication practices to avoid or minimize the risk of a patient’s having a preventable ADE depends on understanding the proximal causes and system failures that occur at each of these phases. Identifying all the factors leading to MEs and preventable ADEs at each of these phases enables institutions to develop strategies to improve safe medication use. Development of the technology used in health care today has evolved around an understanding of the system failures within the medication use process. In general, error reduction at the medication administration node has been a common target for improving patient safety because it is the final stage of the medication use process before the patient receives the medication and therefore lacks review by other health care professionals to potentially intercept the error. Smart pump infusion and barcode medication administration technologies focus on the administration phase to ensure that medications are delivered safely and accurately. Other technologies such as computerized physician order entry focus on the prescribing
stage to eliminate errors associated with illegible handwriting and missing information (e.g., medication route). Unfortunately, use of technology alone does not eliminate all proximal causes and may in fact introduce different factors that lead to preventable ADEs such as workflow work-arounds or not using the technology as intended. Therefore, institutions must evaluate each of the process nodes for continuous process improvement because solutions may target various process nodes.

Several studies have evaluated the MEs and ADEs occurring at each stage of the medication use process in ICU patients. One study using a direct observation technique found that the rate of preventable ADEs was highest in the prescribing phase (77%), followed by the administration phase (23%). Although no ADEs were identified in the transcription and distribution stages, several potential ADEs were intercepted at the administration node. A prospective, multicenter study evaluated preventable ADEs identified by two methods. Pharmacists observed prescribing and transcription orders during patient care rounding, and a study physician coordinator solicited reports from health care professionals for all aspects of the medication use process. The investigators reported ADE events by the medication use process node: prescribing (62.5%), administration (33.3%), transcription (4.1%), and dispensing (0%). By contrast, a subgroup analysis of ICU patients in the ADE Prevention Study, a prospective study that identified ADEs using solicited and self-reported incidents and chart review, found the most common node of ADEs and potential ADEs to be the administration phase (44%), followed by the prescribing phase (38%). These studies show that although preventable ADEs may occur at any stage of the medication use process, medication ordering and administration remain the highest-risk stages. However, the rate of errors at each medication process node may vary depending on the technology (e.g., computerized physician order entry, smart infusion pumps) available at an institution; thus, contemporary rates may be different. The proximal causes leading to these MEs are different between these two stages. Lack of drug knowledge, lack of communication, and inadequate monitoring have been determined as
the underlying causes contributing to MEs in the ordering phase, whereas memory lapses and inappropriate techniques are common during the administration phase.\textsuperscript{25,27} An improvement strategy depends on the process node as well as on the factors identified as contributing to preventable ADEs. Therefore, it is imperative that health care institutions evaluate system failures at each of these process nodes to identify sustainable improvement strategies.

**ICU Population at Greater Risk**

Critically ill patients are at a higher risk of having an ADE than are non-ICU patients.\textsuperscript{14} Factors contributing to this increased risk have been correlated with the complexity of the patients, medications, and environment in an ICU setting (Table 49.2).\textsuperscript{20,29,30} Patient-specific characteristics such as advanced age or prolonged hospitalizations increase the risk of an ADE.\textsuperscript{20,29,30} A cross-sectional study identified 230 ADEs in 79 ICU patients. Severity of illness was found to be a risk factor for patients having an ADE. The mean SOFA (Sequential Organ Failure Assessment) score for patients with an ADE was significantly higher than for patients without an ADE (10 vs. 8, respectively, \(p<0.001\)).\textsuperscript{31} Other possible risk factors for an ADE were patients requiring mechanical ventilation and those with renal dysfunction, continuous sedation, or vasoactive support.\textsuperscript{31} Furthermore, a retrospective case-control study of ICU patients at an academic medical institution found that the highest risk of an ADE was in patients with AKI (OR 16.2, 8.13–32.28), followed by thrombocytopenia (platelet count less than 100,000 mm\(^3\)) (OR 2.93, 1.56–5.48) and emergency admissions (OR 2.04, 1.04–4.00).\textsuperscript{20}

The number and complexity of medications used in the ICU is also a major risk factor leading to increased MEs and ADEs. The Institute for Safe Medication Practices defines a “high-alert” medication as an agent carrying an increased risk of causing patient harm when used erroneously.\textsuperscript{20} These are medications with complex dosing strategies, narrow therapeutic indices, and unique administration techniques and medications that require intense monitoring to ensure safe and effective
use. Therapeutic drug classes commonly associated with MEs and ADEs include cardiovascular agents, anticoagulants, sedatives, and antimicrobials. High-risk medications are a risk factor for adverse event development, with as much as a 3 times greater odds of developing an ADE with each additional high-risk medication. A multicenter, observational study of medical ICUs among three academic medical facilities did not observe that “off-label” medication use alone was a risk factor for an ADR. However, the ADR rate increased by 8% for each additional medication used in an “off-label” manner. Parenteral drugs and the number of high-risk medications administered are also independent risk factors for MEs and ADEs in the ICU. Critically ill patients are more commonly exposed to intravenous medications and prescribed more drugs than are general ward patients.

The fast-paced nature and complexity of critical care services provided are variables possibly leading to errors and adverse events. A potential relationship between nursing resources and adverse events exists. Seynaeve et al. completed a retrospective chart review looking at specific drug triggers and found that patients with at least one ADE had a significantly higher nursing workload and activities than did those without an ADE (p=0.002). Furthermore, any lack of communication among health care providers involved in the care of the ICU patient may pose the risk of an ME or ADE. Several providers are often involved in the care of critically ill patients, which may be a challenge when integrating seamless care among all healthcare providers. Physician staffing models and work hours in the ICU are another important factor that may increase the risk of errors.

**Common ADEs**

Several medications are implicated in the development of ADEs commonly experienced by the critically ill patient. Thrombocytopenia may occur in more than 50% of ICU patients, and up to 25% of these cases are reported to have drug-induced causes. Several medications are implicated in the development of thrombocytopenia.
Heparin is the most common agent associated with drug-induced thrombocytopenia in critically ill patients. About 10%–20% of patients on heparin may experience the nonimmune-mediated reaction of heparin with no significant clinical sequelae, despite therapy continuation. Although the incidence of immune-mediated heparin-induced thrombocytopenia is lower (1%), about 30%–80% of these patients develop a thromboembolic event. Several antibiotics commonly used in ICU patients, including, but not limited to, β-lactams, linezolid, and vancomycin, have been associated with thrombocytopenia. Linezolid, with an incidence of about 2%, potentially carries a higher risk than other antibiotics. In postmarketing surveillance, the incidence increases to 5% in patients receiving more than 14 days of therapy. Of interest, one post hoc analysis from two prospective, randomized, multicenter studies evaluated the risk of thrombocytopenia in patients treated with linezolid for nosocomial pneumonia. In this study, the incidence of thrombocytopenia in the linezolid group was low and not significantly different from that in the vancomycin group (2.8% and 3.6%, respectively).

Acute kidney injury is another common adverse event seen with commonly used medications in the ICU. The incidence of drug-induced AKI is about 20%–30% in ICU patients and may be as high as 60% in older adult patients. An extensive list of medications is associated with AKI (Table 49.3). The incidence of aminoglycoside-induced AKI exceeds 50% in the ICU, although according to estimates that are more conservative, the incidence is 10%–20%. Drug-induced AKI from amphotericin B is reported to be as high as 80%, although the true incidence may vary depending on the prevention strategies used. Identifying drug-induced causes is difficult because most ICU patients have other factors possibly contributing to AKI. Moreover, the variability in definitions of AKI used in these reports may influence the true incidence.

ICU = intensive care unit.

Oversedation and hypotension associated with sedatives are also common in ICU patients. Several studies show that a high proportion of the ICU patients who require continuous sedation are oversedated. One observational study identified that about 41%–57% of ICU patients were sedated deeper than they should have been, depending on the day the sedation assessment was completed, and another investigation found that about 30% of ICU patients were unresponsive.37-39 Several causes contribute to sedating an ICU patient deeper than the clinician’s goal level. The lack of a sedation protocol targeting light sedation levels and the nonadherence to such protocols in institutions with already established sedation protocols may be reasons contributing to oversedation.37 Another reason may be that the critical care clinician is
not considering the pharmacokinetic/pharmacodynamic properties of these agents in patients with renal and/or hepatic dysfunction, as well as obesity. Another common ADE associated with sedation is hypotension. The incidence is variable, depending on the specific agent evaluated and the definition used.

Drug-induced bleeding attributed to anticoagulants and thrombolytics remains a serious concern in the critically ill population. Prophylactic low-molecular-weight heparin has been shown to cause bleeding in 10%–25% medical-surgical ICU patients, with about 5% of the cases considered major bleeding. A prospective, multicenter trial compared thromboprophylaxis with low-dose unfractionated heparin to dalteparin in 3,746 ICU patients. Intention-to-treat analysis found no significant differences between heparin and dalteparin for any bleeding (13.2% vs. 13.0%, respectively; p=0.93) or major bleeding (5.6% vs. 5.5%, respectively; p=0.98). Major bleeding from prophylactic low-molecular-weight heparin in trauma patients is about 0.8%–3.5%, with up to 19% of patients having some type of bleeding when low-molecular-weight heparin is initiated within 48 hours after injury. Therapeutic anticoagulation and its associated risk of bleeding is lacking specifically in the ICU population, although the rate of any bleeding has been estimated to be 5%–20%. The incidence of major bleeding attributed to thrombolytic use for pulmonary embolism varies. Some randomized controlled trials showed no major bleeding events, whereas others found rates approaching 30%. Analyses of pooled data from these trials found major bleeding rates from thrombolytics to be 9.1%, and some bleeding occurred in 22.7%.

Unfortunately, the true incidence of these common ADEs remains unknown. These ADEs are often multifactorial in complex ICU patients with several comorbidities, so pinpointing the cause to a specific medication remains a challenge. Furthermore, these rates may vary depending on the agent, dose, and definition used for these ADEs in published reports. Most studies evaluating the incidence of ADEs used expert evaluation of incidents to determine whether an ADE occurred. Use of pharmacovigilance algorithms (e.g., Naranjo, Kramer, Jones) may help improve the ability to determine the causality of a drug-
induced ADE in critically ill patients. Strategies used in managing the ADE beyond supportive care may largely depend on the severity of the ADE and the extent of complications experienced by the patient. The first step typically includes discontinuing the suspected medication, identifying an alternative drug, and determining the benefit-risk ratio of continuing the suspected agent. A reduction in the dose of the suspected or known medication may alleviate some ADEs as well.

**ACTIVE SURVEILLANCE**

As pharmacists, we need to be the leaders in the active surveillance of MEs and ADEs. The ideal surveillance system is multifaceted, including both retrospective and prospective approaches (Table 49.4). Retrospective surveillance allows events to be detected after they have already occurred and often after the patient is discharged from the hospital. The advantage to retrospective surveillance is the compilation of data that allow for rigorous and structured evaluation (i.e., a root-cause analysis) to prevent future events. Prospective surveillance is completed in real time or as close to real time as possible, often affording the opportunity for intervention and prevention of an ADE or mitigation of ADE severity. Furthermore, retrospective and prospective surveillance can be categorized into targeted and non-targeted chart review. Non-targeted chart review requires a comprehensive review of the patient’s medical record to investigate the details of an event. Targeted chart review entails a review of a targeted section of the patient’s medical record or a review of a medical record for a targeted patient. Retrospective and prospective surveillance will be discussed in detail.

**Retrospective Surveillance**

Retrospective surveillance with non-targeted chart review is the most comprehensive approach to event detection with no selectivity or boundaries. Clearly, the disadvantage is the laborious nature of this approach and the resources necessary to execute such a project.
More realistically, patients are randomly selected in a specified time interval (i.e., 20 charts each month) and are possibly representative of a specified patient population (i.e., ICU patients). Another consideration is the need to adequately train those reviewing the charts so that the criteria for consistency can be established. The advantage to this comprehensive, non-targeted chart review is that it detects more events than do other methods of detection, and often, events are representative of those occurring at various stages of the medication use process. A study comparing a comprehensive non-targeted chart review with a prospective trigger method identified 398 actual ADEs and 275 actual ADEs, respectively, and only 76 events overlapped between surveillance methods.

Retrospective targeted chart review that is focused on a specific section of a chart is usually accomplished through triggers. Triggers commonly include antidote medications, abnormal laboratory values, and abnormal serum concentrations. Systems to identify patients receiving antidote medications include reporting the financial records for patients who received an antidote medication using the pharmacy information technology system or tracking patients with a financial transaction for an antidote medication using automated dispensing cabinet reports. Abnormal laboratory data would be tracked using the institution's electronic medical record. The Institute for Healthcare Improvement (IHI) recommends 13 triggers for surveillance in its current medication module, and most triggers are used for detecting severe events. Triggers can be used in a manual format (e.g., pharmacist review) or an automated format; both formats have been used with success. The success of a retrospective chart review surveillance method is measured by the number and type of events detected relative to other detection methods. Retrospective targeted chart review has consistently identified more ADEs in the ICU than have voluntary incident reports. For example, a retrospective targeted chart review of five antidote medications identified 77 events, none of which were voluntarily reported and only seven of which were identified with administrative data. Although more events have been identified with a comprehensive chart review, a targeted approach identifies different events, and in fact, the overlap between targeted and non-targeted review is small, 11% for every one evaluation. In addition, a retrospective targeted chart review using IHI triggers has shown utility in identifying ADEs in the ICU at 228 ADEs for every 1,000 patient-days or one ADE for every four admissions.

<th>Methods of Detection</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Incidence reports

- Voluntary reports by health care professionals
- Applied to retrospective and prospective surveillance, but real-time intervention with prospective surveillance is a challenge without a timely review and dedicated resources

Non-targeted chart review

- Comprehensive review of a patient’s medical record to investigate the details of an event
- Applied to retrospective and prospective surveillance, but real-time intervention with prospective surveillance is a challenge without a timely review and dedicated resources

Targeted chart review

- A review of a targeted section of the patient’s medical record or a review of a medical record for a targeted patient
- Applied to the both retrospective and prospective surveillance, but the approach may vary
- Retrospective approaches include:
  - Section of the chart (i.e., discharge summary)
  - Administrative data
  - Triggers
- Prospective approach includes:
  - Triggers

Direct observation

- View nurses’ administration of medications with detailed documentation of the entire activity by a trained observer, and the data are later evaluated for medication errors
- Applied as prospective surveillance because observed in real time but evaluated later for errors, so immediate patient intervention does not occur

Patient/family communication

- Patient and family engagement to report events
- Application to prospective surveillance would be ideal and would allow an opportunity for intervention with sufficient resources

Pharmacist surveillance

- Pharmacist participation in and surveillance of drug ordering and monitoring
- Applied to prospective surveillance and allows for real-time intervention

To optimize the triggers used for a retrospective review, triggers
should be evaluated for their performance. A performance characteristic quantifies how well the trigger performs at identifying an ADE. Performance characteristics are reported as the number needed to alert, positive predictive value (PPV), negative predictive value, sensitivity, and specificity.\textsuperscript{49,54} The performance of five antidote triggers for detecting ADEs in a medical ICU was as low as a PPV of 0.02 for methylprednisolone and as high as a PPV of 0.52 for sodium polystyrene.\textsuperscript{52} Of importance, performance characteristics of triggers may be expected to vary by patient care environment and should be tested for each. A trigger such as corticosteroids may be less specific for an ADE with a lower PPV in the ICU than in a non-ICU because there may be greater use for corticosteroids in the ICU. Little work has been done to compare performance characteristics of triggers between ICU and non-ICUs, and of the work done so far, no aberrant differences have been noted, but more triggers need to be considered.\textsuperscript{55} Another consideration on trigger performance variation is the use of triggers for retrospective or prospective ADE detection because the retrospective approach may have more definitive objective data to analyze at the time of the trigger evaluation.\textsuperscript{44}

Retrospective targeted chart reviews can be focused on specific patients or sections of the chart that are not prompted by a trigger. For example, there may be a need to target all ICU patients or to target patients receiving a specific drug or drug class (i.e., opioids). A priority patient population, such as older adults, may be of interest to your institution, thus generating the need for additional surveillance of these patients. Targeted chart review for specific populations could include tracking administrative data or ICD-9 codes for ADEs known as E-Codes.\textsuperscript{56} In addition, surveillance could include a retrospective chart review for an evaluation of the section of the chart on the day of transfer from an ICU to a non-ICU; this would be a targeted population and a targeted section of the chart. A review of the transfer summary revealed many more ADEs that occurred in the ICU than in hospital discharge summaries.\textsuperscript{57,58}

The type of surveillance that most institutions rely on are incident reports.\textsuperscript{59} Unfortunately, only a small number of events are reported by
hospital staff using incident reporting.\textsuperscript{48,60} Incident reports can be a type of retrospective targeted chart review, but many institutions do not conduct a chart review for incident reports. Moreover, with minimal investigation performed, the reports are only taken at face value and therefore do not qualify as targeted chart review. However, incident reports are still considered retrospective surveillance. Ideally, to maximize the benefit of incident reports, some investigation for a root cause should be conducted. Federal regulations mandate the reporting of serious events to the state.\textsuperscript{61} In addition, the Joint Commission has minimum requirements for incident reporting of sentinel events to this organization.\textsuperscript{62} Incident reports can detect events across the gamut of the medication use process. This method of surveillance is one of the least expensive approaches; however, it consistently detects fewer events than other methods because of poor reporting by health care professionals.\textsuperscript{45} Institutions that rely on incident reports for the sole source of event detection should try to maximize reporting. Make it as easy as possible by streamlining the process, using automation, providing feedback for reported events, using incentives, and ensuring a no-blame policy.

**Prospective Surveillance**

Prospective surveillance is usually done in a targeted manner using trigger alerts from clinical decision support (CDS) as the impetus for event investigation. Alerts can be applied manually, or they can be automated.\textsuperscript{51} Clinical decision support is a type of health information technology that “provides clinicians, staff, patients or other individuals with knowledge and person-specific information, intelligently filtered or presented at appropriate times, to enhance health and health care.”\textsuperscript{63} Clinical decision support using alerts as a trigger to initiate a targeted chart review will be discussed by (1) CDS during the prescriber order entry, (2) CDS during order verification, and (3) CDS for monitoring.

Clinical decision support used to generate alerts during the order entry process are provided to the prescriber. Although these may be used as an impetus to initiate a targeted chart review of limited data
(e.g., weight, other drug orders, laboratory values), they are also used as a prevention tool to reduce the number of MEs associated with inappropriate prescribing. Pharmacists are often engaged in developing alerts with a diverse team of health care professionals and information technology team members to determine the rules or signals for the alerts. Several examples of signals for alerts during the order entry process include ordering a total daily dose of morphine in a patient older than 65 years that exceeds the institution’s limits, ordering a nephrotoxic agent in a patient with a rising serum creatinine concentration, or ordering an epidural medication in a patient receiving an anticoagulant. The alert can have a range of actions, from passive with a simple notification to a hard stop that will prevent the prescriber from continuing the order for possible impending patient harm. Clinical decision support of this type has been useful in reducing MEs from inappropriate prescribing, reducing the timeliness of medication therapy change or discontinuation, and reducing progression to ADEs.\textsuperscript{51,64}

Clinical decision support used to generate alerts during the order verification process originates from homegrown systems and vendor systems. These alerts are still focused on the errors in the prescribing stage of the medication use process. The example most familiar to pharmacists is drug-drug interaction alerts. When pharmacists receive an alert for a possible drug-drug interaction, they are expected to investigate the patient’s chart—at minimum, the patient’s electronic medication administration record—to assess the need for an intervention to prevent an ADE.

Alerts occurring during order verification or prescribing run the risk of substantial alert fatigue. Alert fatigue occurs when a clinician is exposed to several alerts, both true positives and false negatives, and the clinician becomes desensitized to the alerts over time. Reduction in alert fatigue for drug-drug interactions has been tried by refining alerts to avoid signal-to-noise ratio, deploying only alerts that are considered serious events (i.e., a tiered approach), incorporating end-user opinion in developing alerts, and developing rules according to specific patient populations, such as those in the ICU.\textsuperscript{65-67}

Clinical decision support used to generate alerts for drugs during the
monitoring stage will be discussed in two categories: (1) alerts that use laboratory values and (2) alerts that use antidote medications as the signal. These alerts, when used for prospective surveillance, can prevent patient harm if identified quickly enough.\textsuperscript{68,69} If a patient with moderate renal dysfunction has an elevated potassium of 5.7 mEq/L from using a potassium-sparing diuretic and the patient is asymptomatic, an alert can be generated at the intermediate step before the occurrence of patient harm (i.e., an arrhythmia). This CDS intermediate step is a DRHC. If the alert does not generate until this patient’s potassium concentration is 6.8 mEq/L and the patient is having a cardiac arrhythmia, the opportunity to intervene and mitigate the progression of ADEs with prospective surveillance has been missed. At this point, the emphasis is on ADE management, not prevention.

Several laboratory values have been used as the signal for alerts, including electrolytes, international normalized ratio, partial thromboplastin time, and drug concentrations. Alerts using laboratory values require some sophistication to optimize alert performance and reduction in alert fatigue. Laboratory-based alerts were initially designed using a specific value with a broad investigation for drug-related causes. Laboratory-based alerts have become more advanced, with signals/rules that generate the alert for a specified abnormal laboratory value only for a patient who is receiving a drug that is associated with the abnormal laboratory value.\textsuperscript{48,70} In addition, laboratory rule performance can be improved by altering the criteria for the signal with drug-induced thrombocytopenia; this may mean changing the signal from a drop in the platelet count of less than 100,000/mm\textsuperscript{3} to an absolute decrease in the platelet count of greater than 50%, hence changing the PPV from 0.36 to 0.83.\textsuperscript{70} Of note, improving specificity can affect sensitivity. Using antidote medications for ADE prevention is a little more complicated because the antidote can be administered after patient harm has already occurred. Antidote medication alerts for prevention will require dedicated resources, allowing for prompt investigation and a rapid response team approach for timely interventions. Antidote medications that have been used include naloxone and dextrose 50%.\textsuperscript{71}
Other types of monitoring alerts that have been studied relatively less commonly are errors of omission and drug-induced physiologic responses. Agents with narrow therapeutic ranges, including heparin and warfarin, require consistent monitoring; thus, infrequent monitoring or lack of timely monitoring may be an opportunity to generate an alert to ensure safe medication use. Monitoring of drug-associated physiologic abnormalities has been evaluated even less commonly. This requires a CDS that is integrated with the electronic medical record and that can capture the physiologic monitoring in real time. This CDS system can be applied to episodes of drug-induced hypotension in the ICU.6

The success of CDS for prospective surveillance can be measured by ME reduction, ADE reduction, number of interventions, and number of interventions that are considered clinically significant.49,55,71 Consistency in measuring these outcomes will require precise and predetermined definitions. In addition, the performance characteristics of each alert can be measured with alert refinement that is applied accordingly for improvement. This evaluation process will likely require a committed quality improvement program.

In addition to categorizing surveillance by the type of chart review, prospective surveillance by other methods is possible, including direct observation; interviews of patients, families/caregivers, or health care professionals; and pharmacist participation in patient care (rounds and tele-medicine). It is most challenging to identify errors during the administration stage in the medication use process. Surveillance requires direct observation to effectively identify errors. Direct observation is the viewing of nurses administering medications and the provision of detailed documentation of the entire activity by a trained observer. This documentation is later evaluated for MEs by comparing the nurse’s activities with the prescriber’s orders, the institution’s policies, and drug information resources.72,73 Therefore, direct observation allows for prospective surveillance because it is completed in real time, but the goal of this method is not to intervene in patient care at that moment. Direct observation has been effectively applied to the ICU.25,74,75 Engaging patients and their families in patient care is
highly encouraged. Asking the patient about the occurrence of ADEs is a surveillance method that has been effectively applied to settings other than the ICU.\textsuperscript{76,77} Finally, pharmacist participation in ICU patient care for ME and ADE prevention has been evaluated in several studies. In one study, a critical care pharmacist reviewing medication orders for patients admitted to the ICU resulted in a significant reduction in prescribing errors and preventable ADEs.\textsuperscript{78} Pharmacists’ proactive medication recommendations often result in the addition of a drug if an error of omission occurs.\textsuperscript{79} The classic and well-designed study by Leape and colleagues showed that a pharmacist’s participation in patient care rounds reduced ADEs by 66\%.\textsuperscript{80}

Overall, the best surveillance system will include both retrospective and prospective evaluations, with the goal of preventing ADEs for prospective surveillance. The retrospective surveillance will require many methods for identifying the most events because different methods detect different events. Including automation, whenever possible, may more efficiently use resources. It is important to have a process in place that allows for the assessment of the retrospective surveillance data to make future systematic improvements. To ensure the optimal performance of the surveillance system, monitoring through a quality improvement program is essential.

47. Olsen S, Neale G, Schwab K, et al. Hospital staff should use more than one method to detect adverse events and potential adverse events: incident reporting, pharmacist surveillance and local real-time record review may all have a place. Qual Saf Health Care 2007;16:40-4.

LEARNING OBJECTIVES

1. Design a plan for assessing and managing the prophylactic, empiric, and definitive use of antimicrobial regimens in patients with febrile neutropenia.

2. Identify risk factors for developing donor-derived infections, and determine appropriate antimicrobial therapy.

3. Recognize common reasons for intensive care unit admission and common medication issues among HIV-positive patients.

4. Devise a treatment strategy for managing treatment-experienced HIV-positive patients, including the management of common opportunistic infections.

5. Distinguish differences in the diagnosis and treatment of common noninfectious pulmonary complications occurring in immunocompromised patients.

7. Recommend supportive care treatment for posterior reversible leukoencephalopathy associated with calcineurin inhibitors.

# INTRODUCTION
Immune system suppression may occur as a result of the pathophysiology of illness or medications. Diseases such as hematologic malignancies, acute liver failure, or human immunodeficiency virus (HIV) leave hosts functionally immunocompromised, with both the adaptive and the innate immune systems unable to mount the same defensive response as in healthy individuals. Suppression of the immune system may lead to an increased incidence and severity of infections and malignancy. Conversely, a certain degree of immune system suppression may be desirable, in an effort to prevent the rejection of a transplanted organ by host defenses or end-organ damage in the setting of an autoimmune disorder. As both the mechanisms and the degrees of immunosuppression vary, so do the types of related complications. This chapter describes several common clinical challenges faced by pharmacists caring for the critically ill immunosuppressed patient.

INFECTIOUS COMPLICATIONS OF IMMUNOSUPPRESSION

Febrile Neutropenia

Febrile neutropenia (FN) is common, developing in upward of 50% of patients with solid tumors and 80% of patients with hematologic malignancy receiving myelosuppressive chemotherapy. However, only 20%–30% of patients with FN episodes have clinically documented infections. In such patients, common sites of tissue-based infections include the gastrointestinal (GI) tract (enterocolitis, colorectal), lung, and skin and soft tissue. Bacteremia occurs in 10%–25% of patients. Unexplained fevers are common and may arise from chemotherapy or medications commonly used in critically ill patients. In addition, receipt of blood products, withdrawal from opioids or other medications, and development of deep venous thrombosis may be reasons for fever among patients with FN. Even though most patients who develop FN have no identifiable site or microbiologic evidence of infection, all patients with FN, particularly those requiring intensive care, should
receive empiric antimicrobials as soon as possible. The prompt initiation of antimicrobials for patients with FN has been correlated with improved patient outcomes.\(^3\)

**Definition**

Despite the lack of studies evaluating the relative sensitivity and specificity of different definitions of FN, several guidelines provide general criteria as a starting point for identifying patients who may require antimicrobials. According to the Infectious Diseases Society of America and National Comprehensive Cancer Network guidelines, fever is defined as a single oral temperature of 101°F (38.3°C) or greater or a temperature of 100.4°F (38.0°C) or greater sustained for 1 hour. By the same guidelines, neutropenia is defined as an absolute neutrophil count (ANC) of less than 500 cells/mm\(^3\) or an ANC that is less than 1,000 cells/mm\(^3\) and expected to decrease to less than 500 cells/mm\(^3\) during the next 48 hours.\(^2,4\) The specific definitions for determining FN are general guidelines for clinicians. Therefore, given the considerable interpatient variability, clinical judgment is of paramount importance in identifying patients who may require antimicrobial treatment despite not meeting the traditional criteria for FN. For critically ill patients, particularly those with evidence of hemodynamic compromise, clinicians should be more liberal with the definitions of FN and have a higher inclination to provide early antimicrobial therapy. For instance, critically ill patients with neutropenia may be considered for antimicrobial therapy even when having low-grade temperatures that do not meet the traditional definitions of fever.

**Risk Assessment**

Because most patients with cancer admitted to an intensive care unit (ICU) are likely to have signs and symptoms of infection and require treatment, it is beyond the scope of this chapter to discuss the role of prophylaxis. Patients presenting with FN may have drastically different clinical courses, ranging from full recovery to life-threatening medical events. As such, characterizing a patient’s risk of developing serious
infectious complications has both prognostic and treatment implications. Those with the highest risk include individuals with significant medical comorbidity, clinical instability, profound neutropenia (ANC of 100 cells/mm\(^3\) or less), anticipated prolonged neutropenia (7 days or more), evidence of organ dysfunctions, severe mucositis, or a Multinational Association for Supportive Care in Cancer Risk Index score less than 21 (see Table 50.1). All patients requiring admission to the ICU likely fall within the high-risk category for developing serious complications. As such, these patients should be empirically treated with broad-spectrum intravenous antimicrobials and monitored closely. Laboratory tests should involve at least two sets of blood cultures, including one set from each existing lumen of a central venous catheter and peripheral vein site. Additional cultures should be sent if there is a suggestion of other sites of infection. Physical signs and symptoms of infections are usually diminished or absent in patients with FN; therefore, a heightened level of scrutiny and attention should be used when doing a physical examination to assess for different sites of infection.

### Initial Empiric Antimicrobials

In high-risk patients, intravenous empiric antibacterial therapy with an antipseudomonal \(\beta\)-lactam such as cefepime, carbapenem (meropenem or imipenem/cilastatin), or piperacillin/tazobactam is recommended.\(^2,4\) The dose and interval for these agents are often different from those for non-neutropenic patients. See Table 50.2 for suggested doses of commonly used antimicrobials. For most hemodynamically stable patients, monotherapy with an antipseudomonal \(\beta\)-lactam is sufficient. However, for those with hemodynamic instability, consideration should be given to administering combination gram-negative therapy (e.g., aminoglycosides). In addition, an evaluation of local microbiologic epidemiology, resistance patterns, and patient history of colonization and prior infection should be done to determine whether additional or alternative therapies are necessary. Studies that have evaluated the addition of additional gram-
negative agents to antipseudomonal \( \beta \)-lactams for the empiric treatment of FN have largely had equivocal results. In fact, a recent meta-analysis evaluating \( \beta \)-lactam monotherapy compared with the combination of aminoglycosides and \( \beta \)-lactams found higher rates of adverse events (nephrotoxicity), infection-related mortality, and fungal superinfections to be associated with combination therapy.\(^5\) However, few of the studies within this meta-analysis specifically evaluated critically ill patients. Furthermore, in the non-neutropenic septic shock population, the receipt of combination therapy was associated with improved outcomes.\(^6\) Taken together, it appears that combination gram-negative therapy should not be routinely recommended for patients with FN; however, it can be considered for patients with hemo-dynamic instability.

Vancomycin should also be considered as part of the initial empiric regimen for patients with FN having hemodynamic instability.\textsuperscript{2} This is also true for patients with suspected serious catheter-related infection (e.g., chills, rigors, evidence of cellulitis around catheter site), soft tissue infection, and radiographic evidence of pneumonia. Similar to the studies evaluating aminoglycosides, adding additional gram-positive coverage to β-lactam monotherapy has not led to improved outcomes.\textsuperscript{7} Hence, the routine use of vancomycin as part of the empiric regimen cannot be recommended. If vancomycin is initiated, therapy should be reassessed after 2 days and discontinued if a resistant gram-positive pathogen is not discovered.\textsuperscript{2}

Antimicrobial doses administered to patients with FN should be the maximum dose approved according to manufacturer labeling, after adjustments are made for baseline renal dysfunction. Optimizing pharmacodynamics is of critical importance in patients without their innate immune system to assist in combating an infection. There are suggestions in the literature that patients with FN may benefit from targeting pharmacodynamic goals that are more aggressive.\textsuperscript{8} The importance of pharmacodynamic target attainment, implications of the lack of innate immune system, and known pharmacokinetic derangements seen in critically ill patients combine to warrant the use of aggressive antimicrobial dosing strategies (e.g., use of highest allowable dose, extended-interval aminoglycoside dosing). See the chapter on Pharmacokinetic/Pharmacodynamic Considerations for further discussions on this topic.

**Modification and Therapy Duration**

In general, modifications to the initial antibiotic regimen should be guided by clinical and microbiologic data. All critically ill patients with FN should be closely monitored for clinical response, adverse effects, and emergence of resistant infections. The median time to defervescence in patients with FN is usually about 5 days.\textsuperscript{9} Hence, patients who are persistently febrile, but otherwise clinically stable, should not require alterations to the initial antimicrobial agents for the first 4–5 days. Specifically, adding vancomycin for persistently febrile patients within the first 3 days of their FN episode did not lead to a decreased time to defeverescence.\textsuperscript{10} In contrast, patients who develop clinical instability after receipt of initial empiric antibiotics should have their coverage broadened, potentially including a second gram-negative agent and vancomycin, if not initially started.

Patients who are persistently or recurrently febrile despite 4–7 days of broad-spectrum antibiotics should be considered for empiric
antifungal therapy and should undergo further evaluation for the underlying cause of fever depending on patient symptoms (e.g., additional cultures, computed tomography [CT] scans, fungal antigen or serologic markers, Clostridium difficile toxin tests). Empiric fungal coverage should use an agent with mold coverage (e.g., echinocandin, voriconazole, posaconazole, amphotericin). If a patient was previously receiving antifungal prophylaxis with one of those agents, an alternative with a different mechanism of action should be used. Of note, if patient was previously receiving a narrower-spectrum triazole (e.g., fluconazole), switching to a broader-spectrum triazole with mold coverage is appropriate. Although preemptive therapy, where antifungals are withheld until the patient has positive serologic assays, cultures, or radio-graphic findings, is an acceptable choice, it has never been evaluated in critically ill patients. Given the severity of illness in critically ill patients, it seems prudent to administer empiric antifungal therapy for those who are febrile for 4–7 days despite antibiotics. This is particularly true if the duration of neutropenia is anticipated to be prolonged (greater than 10 days).

Stable afebrile patients with microbiologically documented infection during their neutropenic episode should have their antimicrobial regimen narrowed to specifically cover the identified pathogen. The treatment duration for each type of infection is similar to what is recommended in non-neutropenic patients. However, therapy should be continued through the duration of neutropenia until the ANC recovers to greater than 500 cells/mm$^3$. For most patients without documented infections, the gram-negative therapy should continue until the resolution of both fevers and neutropenia, at minimum.2

**Role of Hematopoietic Growth Factors**

The use of hematopoietic growth factors, in conjunction with antimicrobials, for the treatment of FN is controversial. Studies have shown differences in surrogate outcomes (e.g., days of neutropenia, duration of fever, length of stay) with the use of hematopoietic growth factors; however, none has identified a mortality difference.11,12 A recent meta-analysis of 14 randomized controlled studies evaluating
the use of growth factors in patients with FN showed no improvements in overall mortality or infection-related mortality.\textsuperscript{13} However, patients who received growth factors were less likely to require hospitalization beyond 10 days, recovered more quickly from fever, and had shorter durations of neutropenia and antimicrobial use. Of note, none of the studies included in this meta-analysis specifically evaluated critically ill patients. The interpretation of available data has led to varying recommendations from different guidelines. The current Infectious Diseases Society of America guidelines recommend against the use of growth factors in patients with established fever and neutropenia.\textsuperscript{2} Similar recommendations are made by the American Society of Clinical Oncology guidelines; however, they suggest that growth factors can be considered for patients at high risk of infection-associated complications.\textsuperscript{14} The high-risk criteria listed are similar to those provided earlier in the chapter (e.g., significant medical comorbidity, clinical instability, profound neutropenia, prolonged neutropenia, end-organ dysfunction, severe mucositis, Multinational Association for Supportive Care in Cancer Risk Index score less than 21). No grading of recommendations was provided in this guideline, and the authors acknowledge this as a consensus opinion. Given the considerable controversy and the lack of definitive data, it seems prudent that growth factors should not be routinely used for the treatment of FN. However, for patients with persistent FN at high risk of developing complications, they may be considered. Of note, a survey completed by the American Society of Clinical Oncology, before the publication of the latest iteration of the guidelines, showed a 60% growth factor usage rate for the treatment of FN.\textsuperscript{15}

**Donor-Derived Infection**

**Definition and Epidemiology**

As the need for solid organ transplantation continues to exceed the available supply, criteria for organ donation are expanding. Although this leads to increased organ availability, the pool now includes more
marginal specimens and organs from high-risk donors, which may result in increased infection risk in the recipient. Some donor-derived transmissions are expected, such as cytomegalovirus or hepatitis B, and routine postoperative care addresses these pathogens with prophylaxis or preemptive therapy. Others are unexpected and carry a high risk of morbidity and mortality. Infection transmission is possible when a donor has active infection of any source, including blood, urine, or the central nervous system. The likelihood that transmission resulted from the transplanted allograft is categorized as proven, probable, and possible. Unfortunately, lack of infection recognition and underreporting may limit conclusions about the true incidence of this problem. However, current data suggest that rates of donor-derived infection are increasing. Although infection is likely transmitted in less than 1% of reported cases, the associated morbidity and mortality is significant, as evidenced by an attributable mortality rate of up to 30%.

Recent evidence suggests bacterial pathogens are the most common source of donor-derived infection. Although donor infection with gram-negative bacilli is associated with a greater risk of transmission and poorer patient outcomes, case reports implicate both gram-negative and gram-positive organisms. These include several multidrug-resistant strains of Pseudomonas spp. and methicillin-resistant Staphylococcus aureus. Such transmissions have resulted in meningitis and bacteremia with complications including pneumonia, endocarditis, and septic arthritis. In addition to bacterial infections, viral and fungal donor-derived infections have been reported.

**Risk Assessment**

Pharmacists participating in the care of organ donors can assist the multidisciplinary team in recognizing individuals at high risk of transmitting infection. These include individuals with high-risk sexual contacts; those having received treatment for syphilis, gonorrhea, chlamydia, or genital ulcers within 12 months; inmates; intravenous
drug users; and those having undergone dialysis within 12 months.\textsuperscript{22} Heightened awareness of risk may prompt providers to do closer surveillance for clinical, serologic, and microbiologic signs of infection, thus increasing the likelihood of identifying an active infection at risk of transmission through donation. When practitioners caring for a recipient are made aware of the presence of infection in the donor, the pharmacist should help ensure prompt initiation of appropriate antimicrobial therapy and continued follow-up to ultimately determine organism speciation and susceptibilities.

**Role of Antimicrobial Therapy**

Guidelines address the treatment of infected organ donors as well as recipients of these allografts. It is recommended that individuals with bacterial meningitis or bacteremia at the time of donation be treated with targeted antimicrobial therapy for at least 24–48 hours before organ procurement, whenever possible. The organ recipients are recommended to receive antimicrobials to which the isolated organism is susceptible for 7–14 days.\textsuperscript{22} Of note, expanding the spectrum of activity of perioperative antimicrobials to include coverage of organisms known to have been isolated in a donor has failed to prevent transmission in several reported cases. These events reinforce the need for continued targeted antimicrobial therapy beyond routine perioperative prophylaxis. In addition, several cases report the occurrence of donor-derived infections weeks outside the immediate peri-transplant period, after presumed eradication of active infection in the recipient. As such, this must be considered when evaluating transplant patients presenting with acute decompensation in clinical status.\textsuperscript{19,20}

**Human Immunodeficiency Virus**

**Critical Care Management**

Since the initial diagnosis of the first case of HIV infection in 1981,
there have been great changes to the epidemiology, management, and outcomes of these patients. In particular, the ICU treatment of patients with HIV has been revolutionized by the advent of highly active antiretroviral therapy (HAART) and routine use of opportunistic infection (OI) prophylaxis. Before this, admissions to the ICU were commonly associated with respiratory failure from pneumonia, which resulted in high short-term mortality.\textsuperscript{24} However, the use of HAART has led to a decline in the morbidity and mortality associated with HIV, as well as the incidence of OI.\textsuperscript{25} These improvements have led to new and different types of challenges for critical care practitioners. Besides familiarity with OIs, ICU practitioners must now be in tuned to the nuances, adverse effects, and drug interactions of HAART, in addition to the presentation and management of immune reconstitution syndrome.

**Treatment-Naive Patients**

Despite advances in screening and increased public attention to HIV, an estimated 20\% of infected individuals are unaware of their diagnosis.\textsuperscript{26} As such, clinicians should maintain a high level of vigilance to identify patients at risk of HIV. Patients with traditional risk factors for HIV or AIDS-defining diseases (\textbf{Table 50.3}) should receive additional serological testing.

For patients with newly diagnosed HIV who present to the ICU, the decision to initiate HAART is controversial. Studies of stable patients (non-critically ill) consistently show that early administration of HAART leads to better immunologic responses and clinical outcomes. However, the benefits of early HAART initiation must be weighed with the potential of adverse reactions and logistical issues associated with administration in the ICU. Some potential logistical concerns include the lack of oral access or appropriate formulations for feeding tube administration, the inability to access a patient’s long-term commitment and adherence to the regimen, and the high probability of interruptions in therapy. Furthermore, patients in the ICU may have acute organ dysfunctions that increase the risk of potential adverse drug reactions. In general, if consistent therapy cannot be ensured, it is best deferred.

Patients recently initiated on HAART may also develop immune reconstitution inflammatory syndrome (IRIS). Immune reconstitution inflammatory syndrome is characterized by the unexpected worsening of existing OI or the unmasking of previously unrecognized disease when HAART has been recently initiated. This can lead to several acute organ dysfunctions, including worsening respiratory failure requiring mechanical ventilation. The pathophysiology of IRIS is associated with the recovery of the immune system leading to proinflammatory cytokine storm. Risk factors associated with IRIS include the presence of disseminated disease or high antigen load, high baseline viral load, low baseline CD4\(^+\) count, and rapid response to
HAART. Although IRIS can be a severe consequence associated with the initiation of HAART, it is unlikely that treatment-naive patients will have IRIS during their ICU stay. The median onset of IRIS from the initiation of HAART is usually around 1 month; however, much earlier onset has been seen. For patients who present with OI, evidence does not suggest that early administration of HAART is associated with a higher incidence of IRIS, and HAART may decrease the risk of death or new AIDS-defining disease.\textsuperscript{28}

In conclusion, when a patient with a new diagnosis is admitted to an ICU, HAART therapy should be initiated or continued, if possible. This is particularly true if the CD4\textsuperscript{+} count is less than 500 cells/mm\textsuperscript{3} or the patient presents with active OI. Data analyses consistently show that earlier treatment is associated with improved outcomes. However, if clinicians cannot ensure the consistent delivery of medications due to adverse reactions, drug interactions, drug formulation issues, and/or lack of gastric access, then HAART should be withheld.

\textbf{Treatment-Experienced Patients}

Patients admitted to the ICU already on HAART represent a different set of challenges. Once again, the decision to continue HAART largely depends on the ability to safely and consistently administer therapy. Route of administration, new renal or hepatic impairment, and the potential for treatment interruptions must be considered. If one of the antiretroviral therapies cannot be safely administered, all therapies should be discontinued to decrease the promotion of resistance.\textsuperscript{29} The possible exception to this rule is for patients chronically on nonnucleoside reverse transcriptase inhibitors, which have long half-lives (about 3 weeks). In these patients, discontinuing all HAART may functionally equate to receiving nonnucleoside reverse transcriptase inhibitor monotherapy; therefore, clinicians should consider continuing to administer other antiretrovirals with shorter half-lives to minimize possible selection for nonnucleoside reverse transcriptase inhibitor resistance. In addition to these considerations, ICU clinicians caring for HIV-positive patients should be cognizant of the common interactions between antiretrovirals and medications commonly used in critically ill
See Table 50.4 for examples.

Another cause for ICU admission among patients with HIV may be HAART-associated adverse reactions. Although newer generations of HAART are usually well tolerated, many patients remain on older antiretrovirals. Hence, clinicians should readily recognize the possible adverse effects associated with HAART. Furthermore, many of the HAART-associated adverse effects have no specific treatments; therefore, prompt discontinuation of the offending agent is crucial.

Despite advances in the management of HIV, a combination of two nucleotide/nucleoside reverse transcriptase inhibitors (NRTIs) remains the backbone of many HAART regimens. Many NRTIs may cause lactic acidosis by disrupting mitochondrial replication through inhibition of DNA polymerase. Mild hyperlactatemia is common in patients receiving NRTIs; however, severe lactic acidosis can also occur and may be life threatening. Before the formulation of newer NRTIs, the rate of severe lactic acidosis occurred at a rate of 1.3 cases per 1,000 person-years of exposure. The risk of developing severe lactic acidosis is highest among older NRTIs, particularly zidovudine, stavudine, and didanosine. The symptoms of severe lactic acidosis are nonspecific and include fatigue, malaise, nausea, vomiting, and abdominal pain. Hence, a high level of vigilance is needed to identify patients who are at risk. The treatment of severe lactic acidosis is largely supportive and entails prompt discontinuation of the possible offending agent.

Another adverse effect of concern commonly seen with older antiretroviral therapy is abacavir-associated hypersensitivity. Up to 3% of patients on abacavir may have such a reaction within a few weeks of initiating therapy. The initial presenting symptoms include fever, rash, and GI symptoms. Treatment involves prompt discontinuation of therapy and supportive care. Patients with ongoing or worsening symptoms should be evaluated for other causes. Hypersensitivity is more prominent among patients with the presence of an HLA-B*5701 allele, which has an 8% prevalence among whites in North America. Rechallenging patients with established hypersensitivity is strictly contraindicated because severe life-threatening hypersensitivity has been reported. Other severe life-threatening adverse drug reactions
among antiretrovirals include Stevens-Johnson syndrome and hepatic necrosis syndrome associated with nevirapine, rhabdomyolysis associated with raltegravir, and intracranial hemorrhage associated with tipranavir.

**Opportunistic Infection: Prophylaxis and Treatment**

The discussion of opportunistic infections (OIs) will cover Pneumocystis jiroveci pneumonia (PJP), Toxoplasma gondii encephalitis, and Mycobacterium avium complex (MAC). Other OIs such as candidiasis, cryptococcal meningitis, herpes simplex virus, and cytomegalovirus can be found in the Invasive Fungal Infections and Invasive Viral Infection chapters. Although the discussion of OIs will largely focus on HIV-positive patients, with the increasing number of critically ill immunocompromised patients with solid organ transplant and cancer, these infections are increasingly seen in HIV-negative patients. In general, management of OI in HIV-positive patients can be extrapolated to patients without HIV.

**P. jiroveci Pneumonia**

Pneumocystis pneumonia is caused by P. jiroveci, a ubiquitous fungal organism known to cause severe respiratory infections in immunocompromised host. The advent of HAART and prophylaxis has dramatically decreased the incidence of PJP, with most cases occurring in patients who are unaware of their HIV status or those not receiving or nonadherent to their HAART regimen.  

Patients with PJP commonly present to the ICU with respiratory distress that is characterized by progressive dyspnea and nonproductive cough in the preceding days to weeks. Hypoxemia is common and can range from mild to severe. Patients with severe hypoxemia and large alveolar-arterial oxygen difference may require mechanical ventilation. Chest radiograph usually reveals diffuse, bilateral infiltrates.

Because the presentation, laboratory findings, and radiographic characteristics of PJP are nonspecific, diagnosis requires
histopathologic or cytopathologic identification of the organism from an induced sputum, bronchoalveolar lavage, or lung biopsy specimen. Traditionally, because the organism does not grow readily with routine microbiologic techniques, laboratories have relied on several different staining techniques. Recent development of a PJP polymerase chain reaction (PCR) test may provide an additional method for identifying PJP. The sensitivity of the PJP PCR is high; however, its specificity for distinguishing true PJP infection from colonization is low; hence, it should function as a rule-out test.33,34

Prophylaxis

Patients with HIV having a CD4+ count less than 200 cells/mm3 or a history of oropharyngeal candidiasis should receive chemoprophylaxis against PJP. Trimethoprim/sulfamethoxazole 1 double-strength tablet once daily is the preferred prophylactic regimen because this dose also confers prophylaxis against toxoplasmosis and other respiratory bacterial infections.33-37 Because trimethoprim/sulfamethoxazole is such an effective agent against PJP, patients with a history of mild to moderate adverse drug reactions should be rechallenged or undergo desensitization. However, trimethoprim/sulfamethoxazole may also cause life-threatening reactions such as Stevens-Johnson syndrome or toxic epidermal necrolysis, which would necessitate discontinuation of therapy with no further exposure to the medication. For these patients, alternative prophylactic regimens such as dapsone or nebulized pentamidine may be considered. Patients with HIV admitted to the ICU should be assessed to ensure that prophylaxis is continued or initiated. Although there are criteria for discontinuing OI prophylaxis, they are usually not applicable in an ICU setting.

Treatment

The treatment of choice for critically patients with PJP is high-dose intravenous trimethoprim/sulfamethoxazole (15–20 mg/kg of trimethoprim divided every 6–8 hours), adjusted for renal function.33-37 Intravenous pentamidine 4 mg/kg once daily may be used in patients with previous severe adverse effects or allergic reactions associated
with trimethoprim/sulfamethoxazole; however, this drug is associated with significantly more adverse effects, including pancreatitis, GI discomfort, nephrotoxicity, and dysglycemia. Oral regimens, such as equivalent doses of oral trimethoprim/sulfamethoxazole or clindamycin/primaquine, should only be used in patients with no known drug absorption issues and those with clinical improvement. Treatment of PJP should be continued for a total of 21 days. Patients with moderate to severe disease complicated by hypoxemia (Pao$_2$ less than 70 mm Hg or alveolar-arterial oxygen gradient of 35 mm Hg or greater) should receive adjunctive corticosteroids. Ideally, prednisone should be initiated within 72 hours of initiating PJP treatment. Those meeting the criteria for severe hypoxemia should have the steroids tapered over the 21-day treatment course (prednisone 40 mg twice daily × 5 days, 40 mg daily × 5 days, 20 mg daily × 11 days). For those without enteral access, methylprednisolone may be used at 75% of the prednisone dose. Adjunctive corticosteroids have been correlated with the attenuation of worsening hypoxemia, which is caused by the rapid acceleration of inflammation from the initiation of anti-Pneumocystis therapy.\textsuperscript{35}

T. gondii Encephalitis

T. gondii is a protozoan organism that may cause encephalitis in immunocompromised patients. Clinical disease is most common among patients with a CD4$^+$ count less than 50 cells/mm$^3$. Infection is almost solely (95%) because of reactivation of latent tissue cysts.\textsuperscript{36} Hence, patients who are immunoglobulin G (IgG) seropositive for antitoxoplasma antibodies are at the highest risk of developing disease. Among adults in North America, the rate of seroprevalence is about 11%. Developing primary disease is possible through exposure to undercooked meat or shellfish containing tissue cysts or oocysts shed from cat feces.

The most common symptoms in patients presenting to the ICU with Toxoplasma encephalitis (TE) are headache, confusion, and motor weakness. Brain imaging typically reveals many lesions within the cerebral cortex or ganglia. Definitive diagnosis requires detection of the
organism through a CT-guided needle biopsy, although most clinicians rely on a combination of clinical symptoms, radiologic findings, serostatus, and response to treatment as an empiric diagnosis.\textsuperscript{33-37}

Prophylaxis

Patients with HIV having a CD4\textsuperscript{+} count less than 100 cells/mm\textsuperscript{3} should be initiated on a prophylactic regimen against TE. Because active disease is primarily from reactivation of latent cysts, patients who are not IgG seropositive do not require prophylactic therapy. However, if this strategy is used, patients should be retested for serostatus each time their CD4\textsuperscript{+} counts drop below 100 cells/mm\textsuperscript{3}. Trimethoprim/sulfamethoxazole 1 double-strength tablet once daily is the preferred prophylactic regimen. If patients cannot tolerate trimethoprim/sulfamethoxazole, the recommended alternative is dapsone/pyrimethamine plus leucovorin.

Treatment

The preferred treatment of TE is a combination of pyrimethamine, sulfadiazine, and leucovorin.\textsuperscript{33-37} An alternative agent for patients who cannot tolerate sulfadiazine is clindamycin. Aside from the known adverse effects of the earlier regimen, such as hematologic toxicities, rash, and GI disturbances, administration in critically ill patients may be challenging because of the lack of availability of parenteral formulations of pyrimethamine and sulfadiazine. For patients without reliable gastric access, intravenous trimethoprim/sulfamethoxazole (10 mg/kg of trimethoprim divided twice daily) may be considered. In a small study, the use of intravenous or oral trimethoprim/sulfamethoxazole led to similar rates of complete response compared with the preferred therapy of pyrimethamine and sulfadiazine, plus leucovorin.\textsuperscript{37} Patients with a history of seizure disorders may benefit from prophylactic anticonvulsants while receiving acute treatment.\textsuperscript{38} The choice of anticonvulsants in patients with HIV having TE is poorly studied; however, phenytoin is the most widely used. Because of cytochrome P450 (CYP) 3A4 induction by phenytoin and the possible drug interactions leading to decreased concentrations of HAART therapy,
some experts recommend the use of newer antiepileptics, such as levetiracetam. In general, patients respond within 14 days of initiating therapy with improvements in mental status and radiologic assessment. Therapy for TE should be continued for at least 6 weeks, with longer courses indicated if patients have incomplete clinical or radiologic response. Completion of acute treatment should be followed by secondary prophylaxis, which usually entails reduced-dose pyrimethamine, sulfadiazine, and leucovorin, continuing for at least 6 months after recovery of CD4+ counts to greater than 200 cells/mm³.

**M. avium Complex**

M. avium complex are ubiquitous organisms responsible for disseminated, multiorgan disease among patients with HIV. This infection is most commonly seen in patients with HIV having a CD4+ count less than 50 cells/mm³. Symptoms, which include fever, weight loss, fatigue, night sweats, and diarrhea, are usually mild and nonspecific and slowly progress over weeks. Physical examination often reveals a combination of lymphadenopathy, hepatomegaly, and splenomegaly. Confirmatory diagnosis requires isolation of MAC from blood, tissue, or other sterile sites. Of note, routine evaluation of cultures for MAC is not indicated because treatment is not necessary in asymptomatic patients.

**Prophylaxis**

Patients with HIV having a CD4+ count less than 50 cells/mm³ should receive chemoprophylaxis against MAC. Azithromycin and clarithromycin are considered first-line agents. Given the high propensity for drug interactions between clarithromycin, which inhibits CYP3A4, and commonly used ICU medications, azithromycin 1200 mg once weekly may be the preferred regimen. Intravenous therapy may be considered for critically ill patients who cannot tolerate oral therapy. No studies have evaluated the use of intravenous azithromycin for prophylaxis of MAC. Although unlikely to cause adverse reactions, intravenous azithromycin at the same dose will likely lead to
supratherapeutic concentrations because oral azithromycin has a bioavailability of only around 35%. For patients at high risk of developing QT prolongation, an intravenous dose reduction may be prudent.

Treatment

Treatment of MAC should consist of at least two drugs because the development of resistance occurs more readily with monotherapy. The preferred regimen is a combination of macrolide (clarithromycin or azithromycin) and ethambutol 15 mg/kg/day, adjusted for renal function. Some clinicians may consider adding rifabutin as a third agent. Macrolide resistance is increasingly reported among patients with MAC, estimated to be as high as 11% in those previously exposed to macrolides. Hence, resistance testing should be implemented in all patients with MAC, particularly those who have previously received macrolide therapy. Improvements should be seen within 2–4 weeks of treatment initiation. Patients with persistently positive cultures after 4–8 weeks should be evaluated with repeated susceptibility testing, given the possibility for the development of resistance. New regimens should be tailored according to these results and, ideally, involve several agents not previously tried. Perhaps equally important to MAC treatment is the optimization of HAART to improve a patient’s immune function. Therapy for MAC should continue for at least 12 months, though extending the treatment course may be necessary for those without adequate immune reconstitution.

NONINFECTIONOUS COMPLICATIONS OF IMMUNOSUPPRESSION

Pulmonary Complications

Peri-engraftment Respiratory Distress Syndrome

Peri-engraftment respiratory distress syndrome (PERDS), also called
Engraftment syndrome, occurs in about 5% of patients immunosuppressed for blood and marrow transplantation. This complication is characterized by a temperature greater than 101°F (38.3°C), pulmonary infiltrates on chest radiograph, a widespread erythodermatous rash, diarrhea, and hypoxia with oxygen saturations less than 90% on room air. When respiratory function is severely compromised, patients often require ICU admission. This constellation of symptoms typically occurs within 5 days of engraftment (ANC greater than 0.5 × 10^3/mm^3) and in patients without cardiac dysfunction or documented infection, though the latter is difficult to rule out in real time in most clinical situations. Although its pathophysiology is poorly understood, PERDS is thought to result from complex interactions between lung endothelial tissue damaged from chemotherapy and radiation conditioning regimens and cytokines released at the time of neutrophil engraftment. Attributable mortality may be as high as 21%. A diagnosis of PERDS is often made after ruling out other causes of respiratory decompensation, such as infectious pneumonia, transfusion reaction, or pulmonary edema arising from cardiac dysfunction. The relationship between PERDS and diffuse alveolar hemorrhage (DAH) is complex and discussed in detail later in this chapter. In addition to supportive care, steroids can be considered for treatment when respiratory distress is severe enough to require ICU admission. Although data are limited, several reports indicate successful prevention and treatment of this condition with steroid use. At one center, a decrease in the incidence of PERDS was seen when instituting routine prophylaxis with prednisone at 0.5 mg/kg/day on posttransplant days 4–14. Another center retrospectively reported symptomatic improvement and decreased oxygen requirements with the use of methylprednisolone 1–2 g/day for 3 days. Response was usually seen within 1–4 days after treatment. The 3 days of high-dose steroids was followed by a rapid taper, though the exact strategy was not clearly outlined.

**Diffuse Alveolar Hemorrhage**
Diffuse alveolar hemorrhage may occur in the setting of several diseases, including, but not limited to, connective tissue disease, antiphospholipid antibody syndrome, and as a complication of blood and marrow transplantation. This chapter will focus specifically on the clinical presentation and treatment of patients with DAH in the blood and marrow transplant setting.

Although the exact pathogenesis is unclear, it is thought that vascular damage and inflammation from chemotherapy and radiation, combined with host immune-mediated events, contribute to pulmonary microvasculature injury resulting in bleeding and alveolar damage. This occurs in 1%–7% of patients undergoing blood and marrow transplantation and most often manifests in the first month after transplantation, though case reports detail this phenomenon as far as 12 months from transplantation.\textsuperscript{44,45} Widely accepted diagnostic criteria include diffuse pulmonary infiltrates present on imaging and progressively bloodier fluid returns during bronchoalveolar lavage, which have greater than 20% hemosiderin-laden macrophages on cellular analysis.\textsuperscript{46} These macrophages can take 48–72 hours to develop and thus it is possible, though uncommon, for them to be absent if bronchoalveolar lavage is done early in the course of DAH. Conversely, clearance from respiratory secretions may take 2–4 weeks. Symptoms accompanying DAH also include a sudden onset of dyspnea, hypoxemia, fever, and non-productive cough. Hemoptysis is present in about 20% of cases. Confirmatory diagnosis is often difficult, given the similarity with which other pulmonary complications present, including PERDS, graft-vs.-host disease, and infectious and noninfectious pneumonias.

If DAH is suspected, the mainstay of treatment is supportive, maintaining adequate oxygenation and optimizing hemostasis. It has been theorized that steroids may be useful to suppress immune-mediated contributors to DAH; however, their role remains controversial.\textsuperscript{46} A single retrospective cohort of autologous and allogeneic blood and marrow transplant patients compared 43 individuals receiving high-dose steroids (greater than 30 mg/day of methylprednisolone equivalent tapered over days to weeks) with 22
receiving low-dose steroids (30 mg/day of methylprednisolone equivalent or less) or no steroids. Although those receiving high-dose steroids had an improved likelihood of survival to hospital discharge, the small sample size, extreme variability in steroid dosing regimens, and lack of rigorous methodology call into question the significance of these results. In addition, subsequent analyses failed to show any clear survival benefit. Commonly reported dosing strategies provided 500–1,000 mg of methylprednisolone daily for 3 days with tapering strategies individualized to patient response or provider preference. Of note, studies do not report an increased incidence of new infection in the setting of steroid use; however, when evaluating the true safety of steroids, patient-specific characteristics must be considered. In the absence of clinical response to steroid therapy, patients being treated for invasive fungal infection, experiencing significant delirium, and those with severe muscle atrophy or receiving neuromuscular blockade (all common complications in this patient population) may not be ideal candidates for an extended course of high-dose steroids. Although a paucity of data supporting steroid use leaves many practitioners with doubts about the effectiveness of this strategy, the high mortality rates associated with this condition (30%–100%) often result in steroid use as salvage therapy.

**Tumor Lysis Syndrome**

**Definition and Pathophysiology**

Tumor lysis syndrome (TLS) is one of the most common emergencies encountered in the care of patients with hematologic malignancies. Either spontaneously or after initiation of cytoreductive therapy, malignant cells rapidly release their contents, including electrolytes, proteins, and nucleic acids, into systemic circulation, potentially triggering many consequences. Patients may be given a diagnosis of TLS on the basis of laboratory findings or clinical developments according to the widely used Cairo-Bishop classification system (Table 50.5). Given the potential severity of consequences and rapidly
progressive nature of this condition, laboratory TLS should be immediately addressed, even in the absence of symptoms, to prevent deterioration in clinical status.

Risk Assessment

One of the keys to anticipating the potential for TLS and mitigating its consequences is a thorough patient risk assessment. This probability most closely relates to cancer type but is also affected by patient characteristics and supportive care. Patients with hematologic malignancies with a high tumor burden, notably acute myeloid and lymphoblastic leukemia, chronic lymphocytic and myeloid leukemia, and Burkitt and non-Hodgkin lymphoma, remain among the highest-risk populations for developing TLS.\textsuperscript{51} It has also been reported, though uncommonly, in patients receiving treatment for bulky solid organ tumors.\textsuperscript{52,53} Given that tumor burden is typically greatest at the outset of disease treatment, the probability of developing TLS is usually highest during the first cycle of chemotherapy for both hematologic and oncologic malignancies. Clinical status may elevate TLS risk in some cases. For example, patients with preexisting renal dysfunction, hypoperfusion, hypovolemia or those who are receiving nephrotoxic medications are at heightened risk of end-organ damage. Elevated baseline uric acid (UA) concentrations or receipt of exogenous electrolytes contributes to worsening laboratory abnormalities.\textsuperscript{51} In addition, delayed implementation of preventive measures in those predisposed represents a missed opportunity for intervention. Risk recognition and prompt initiation of appropriate pharmacotherapy and supportive care is one area in which pharmacists play a pivotal role on the multidisciplinary care team.

Disease Manifestations

Rapid lysis of malignant cells often results in abrupt serum elevation of electrolytes, commonly phosphorous and potassium. The significance of hyperkalemia is underscored by its potential to cause significant arrhythmias and cardiac arrest. Excess serum phosphorus may lead to
precipitation of renal and extrarenal deposits of calcium phosphate crystals, representing one mechanism of acute kidney injury in TLS.\textsuperscript{49,54} Another complication of hyper-phosphatemia is secondary hypocalcemia, putting patients at risk of neurotoxicity, dysrhythmia, and seizure. Unfortunately, many of these laboratory abnormalities may be augmented in the setting of renal dysfunction, resulting in a greater likelihood of clinical sequelae.

\textsuperscript{a}Values diagnostic for adult patients only.

\textsuperscript{b}Diagnosis requires two or more metabolic abnormalities to be present within same 24-hour period 3 days before or 7 days after initiation of cytotoxic therapy.

\textsuperscript{c}Requires diagnosis of laboratory tumor lysis syndrome in addition to clinical symptoms.
The nucleic acids from the DNA released into the circulation from lysing cells are broken down into hypoxanthine. This is further metabolized to xanthine and then to UA by xanthine oxidase. Rapid accumulation of these products can contribute to acute kidney injury through formation of urate crystals in the distal renal tubules and collecting ducts, obstructing the tubular lumen. The process is potentiated by both an acid environment, due to a decrease in UA solubility, and the presence of calcium phosphate crystals, which causes UA to precipitate more readily. Even in the absence of precipitation, UA activates the renin-angiotensin system, reducing available nitric oxide and resulting in renal vasoconstriction. Rising xanthine concentrations may also cause nephropathy or urolithiasis, regardless of pH.

Crystal-independent mechanisms play a role in acute kidney injury as well. Lysed malignant cells spill cytokines and chemokines into circulation, and these inflammatory mediators induce local vasoconstriction at the level of the kidney. Reduced renal perfusion and hypoxia add to the tubular injury caused by crystal precipitates.

**Prevention and Treatment**

Risk assessment and proactive implementation of preventive measures in high-risk patients remain the keys to detecting TLS and mitigating the severity of sequel-ae. Aggressive hydration and brisk urine output enhance excretion of UA and phosphate through expansion of intravascular volume and improvement in renal blood flow. Maintaining renal perfusion is also important in protecting the kidneys from ischemic injury. If tolerated, consider administering crystalloid fluids at a rate of 2.5–3 L/m²/day. The choice of fluids should be individualized according to the patient’s clinical status. For example, chloride-poor products such as Ringer lactate may more desirable than normal saline, given the latter’s potential to perpetuate an acidic environment. However, in patients with preexisting severe hyperkalemia, Ringer lactate should be avoided in large volumes; goal urine output remains 3–5 mL/kg/hour. After ruling out obstructive renal injury, loop diuretics may be used to maintain this goal urine output in the setting of
adequate intravascular volume. Of note, urinary alkalinization is no longer recommended for TLS prevention, given a lack of evidence supporting its efficacy. Although UA is more soluble in a basic environment, this increases the risk of precipitation of calcium phosphate crystals. Furthermore, xanthine, the precursor to UA, has low solubility, regardless of pH.

By preventing the metabolism of nucleic acids via xanthine oxidase, allopurinol can help circumvent accumulation of UA and hypoxanthine and the resultant renal injury. Of note, doses for TLS prevention are typically higher than those used in the treatment of gout. Guidelines suggest initiating allopurinol at 50–100 mg/m$^2$ orally three times daily or at 10 mg/kg/day given in divided doses. The maximum recommended oral daily dose is 800 mg. Although general dosing guidelines advocate for a 50% dose reduction in patients with significant renal impairment, the benefits of aggressive dosing in maintaining or recovering renal function must be considered. In the absence of clear allopurinol-related toxicity, data analyses do not support dose reduction in this population. Therapy should start 12–24 hours before cytoreductive treatment and continue until normalizations of UA concentrations, leukocyte count, and laboratory values occur and the tumor burden is significantly decreased.

Routine electrolyte monitoring and prompt management of derangements when identified reduce the risk of deleterious clinical effects. Serum chemistries including UA, potassium, phosphate, and calcium should be monitored every 6 or 8 hours in patients at a high or moderate risk of TLS. Electrolyte, UA, and creatinine abnormalities are most likely to be appreciated within 48 hours of cytoreductive treatment. It is also important to evaluate patients’ medication profiles for external sources of these substrates, such as dietary in-take, maintenance fluids, or multivitamins. Phosphate binders may be used in patients with hyperphosphatemia, though calcium-containing products should be avoided in the setting of hypercalcemia. In cases of severe electrolyte abnormalities or clinical manifestation thereof, emergent dialysis may be considered.

Rasburicase is an intravenous medication that catalyzes the
oxidation of UA to the inactive and soluble product, allantoin. It may be used for the prevention of hyperuricemia or, in the event of early detection, before the manifestation of renal injury. For patients already experiencing a decline in renal function, rapid metabolism of UA may mitigate further damage, with the ultimate goal being to avoid the need for dialysis.\textsuperscript{51,57,58} Uric acid concentrations are noted to decrease as soon as 4 hours after a single administration of rasburicase and may continue declining for up to 72 hours.\textsuperscript{57,59,60} Initial investigations studied treatment success with doses of 0.15–0.2 mg/kg given daily for up to 5 days.\textsuperscript{57,58} However, studies that are more recent show equivalent efficacy with fixed doses of 3 or 6 mg, with an infrequent need for repeat dosing. This represents a significantly more cost-effective strategy, optimizing health care resources.\textsuperscript{58-61} The drug properties of rasburicase are such that it is removed by dialysis; therefore, it may be prudent to avoid administration in patients for whom dialysis is imminent. When considering the use of rasburicase, note its contraindication in patients with G6PD (glucose-6-phosphate dehydrogenase) deficiency, given the potential for severe hemolysis in some patients.\textsuperscript{57} Proactive identification of patients at highest risk of TLS who may benefit from rasburicase allows for appropriate testing before initiating cytoreductive therapy. In addition, proper technique is required for accurate laboratory monitoring of UA after an administered dose. To avoid enzymatic degradation of UA by rasburicase, blood samples must be stored in pre-chilled, heparin-containing tubes; kept refrigerated; and analyzed immediately by laboratory personnel.

**Acute Calcineurin Inhibitor–Associated Neurotoxicity**

**Epidemiology and Pathophysiology**

Although a valuable component of modern immunosuppression, calcineurin inhibitors (CNIs) carry a risk of several troublesome adverse effects. This class of immunosuppressants is commonly used for rejection prevention after solid organ transplantation, graft-vs.-host disease suppression after blood and marrow transplantation, and
management of various other disease states that require immune modulation. In addition to nephrotoxicity, neurotoxicity is one of the most commonly encountered adverse effects of CNIs, with serious events reported in up to 43% of patients. Arguably, the most severe of these is posterior reversible leukoencephalopathy syndrome (PRES).

There are two proposed mechanisms for the pathology behind PRES. The first describes T-cell activation, which initiates a cytokine response. Resultant inflammation damages vascular brain endothelium, leading to vasogenic edema and ultimately tissue hypoperfusion. This process may be precipitated by several concomitant comorbidities such as infection, hypertension, preeclampsia, or organ rejection. Second, severe systemic hypertension may lead to transient disruption of autoregulation, a consequence of which is cerebral vasodilation. This allows fluid and blood into brain parenchyma, causing cerebral edema. Evidence of these events can be seen with CT or magnetic resonance imaging, which is considered the gold standard for syndrome diagnosis.

Symptoms commonly associated with PRES include encephalopathy, elevated blood pressure, and seizure activity. Encephalopathy ranges from mild disruption of consciousness or lethargy to severe agitation or coma. Reports describe seizures commonly preceded by vision changes or headache. Hypertension is often considered a hallmark of the clinical presentation of PRES associated with any cause; however, reports clearly indicate it is not present in all cases. Mean arterial pressure can exceed 115–130 mm Hg in some cases, but epidemiologic data suggest that around 50% of cases present with normal or only slightly elevated blood pressure. It is thought that the risk of PRES is highest within the first 30 days of CNI therapy, although reports detail cases occurring as many as 10 months after drug initiation. In some instances diagnosis is made when CNI blood levels are considered elevated beyond normal limits (greater than 12–15 ng/mL in most cases) or as a result of rapidly increasing concentrations. This is not universally the case, however, because literature reveals frequent occurrence with normal CNI blood
concentrations. This can indicate that blood concentrations may not accurately reflect those present in the brain.65

**Treatment**

Practitioners must thoroughly evaluate patients for potential causes of PRES aside from CNI therapy. If a CNI is determined to be the cause or a contributor, syndromal reversal ultimately depends on adjustment of CNI therapy in the form of dose reduction or discontinuation. When PRES is first recognized, providers commonly withdraw these medications. Pharmacists should assist in evaluating the appropriateness of an alternative treatment approach, if one is available for the underlying disorder. For patients in whom CNI therapy is overwhelmingly favorable, several case reports detail successful resolution of symptoms with a reduction in the target blood concentration or switching to a different medication within the same class.66,68,70 If these strategies are chosen, the patient should be closely monitored for signs of PRES during the initial reintroduction of CNI therapy. Symptomatic management should include cessation of seizures, hemo-dynamic stabilization, and electrolyte optimization. Seizures should be managed initially with benzodiazepines or alternatively phenytoin, which may induce metabolism of CNIs. Other antiepileptics can be considered for refractory status epilepticus.71 Blood pressure should ideally be maintained at the patient’s premorbid baseline. Given the suspected role of cerebral hypoperfusion in the patho-physiology of PRES, rapid overcorrection and persistent hypotension should be avoided. Overall symptomatic improvement may lag behind normalization of CNI blood concentrations, given the slow transit of CNIs across the blood-brain barrier, but is typically seen within several days of treatment.72 Resolution of radiographic evidence of PRES may be further delayed or occasionally persist, showing permanent cerebral volume loss.

**CONCLUSION**

Immune system suppression, whether as a result of disease or
medication, is seen in a variety of patients, and pharmacists play a pivotal role in the optimization of their care. This may include prompt recognition of opportunistic and other infections, initiation and monitoring of antimicrobial therapy, assessment of indications for infection prophylaxis, maintenance of the balance between immunosuppressive medications and host defenses, and identification of possible adverse drug reactions associated with therapy. By familiarizing themselves with the unique complications seen in critically ill immunocompromised patients, pharmacists can continue to contribute to multidisciplinary health care in distinct and significant ways.

INTRODUCTION

Patients in critical care settings are highly susceptible to adverse drug reactions (ADRs), mainly because of pharmacokinetic (PK) and pharmacodynamic (PD) changes. Adverse drug reactions are a significant public health concern leading to increased mortality, hospital admissions, length of stay, and health care costs. Inadequate therapeutic response to many commonly used drugs is also a common occurrence because medications are often prescribed using a “trial-and-error” approach in the intensive care unit (ICU). The same is true for drug dosing in the critically ill, which largely remains a “one-size-fits-all” approach that is based on studies of healthy volunteers and less-complicated patient populations. Genetic variation contributes to interindividual differences in drug disposition, response, and toxicity, and as such, pharmacogenetic testing may reduce ADRs and increase therapeutic effectiveness. This chapter will review the available evidence for pertinent genetic variants that influence the PK, PD, and ADRs of drugs used in ICU patients. Current recommendations for pharmacogenetic testing in clinical practice and an exploration of drug, patient, regulatory, and practical issues that presently limit more widespread implementation of pharmacogenetic testing will also be discussed.
EMERGENCE OF CLINICAL PHARMACOGENOMICS

Pharmacogenetics is the study of the relationship between single gene variants (i.e., polymorphisms) and variability in drug disposition, response, and toxicity.\(^1\) Pharmacogenomics represents an expansion of the field and includes the study of variants in a large collection of genes, up to the whole genome.\(^1\) A summary of common genetic terms is provided in Box 51.1.

Pharmacogenetics and pharmacogenomics are both subsets of personalized (precision) medicine, with the goal of identifying patients who should not receive certain drugs or who should receive modified drug dosing because of inherited genetic variants. Interest in pharmacogenomics, as evidenced by the many publications in the field, has increased in the past 20 years. This growing body of literature provides many examples of significant alterations in drug metabolism, drug transport, and drug-gene interactions caused by variants in the respective genes.\(^3\) Despite a common belief that the field represents a future innovation, pharmacogenetics has been detailed in the medical literature since the early 1950s. Historically, pharmacogenetic studies examined the association between single gene variants, PK parameters (e.g., excessive exposure), and ADRs. From a research perspective, most pharmacogenetic investigations have used a candidate gene approach whereby prespecified genetic variants and their association with a phenotypic trait of interest were evaluated. One notable feature of this approach is the need for prior knowledge of the most likely mechanisms underlying drug disposition, response, or toxicity. However, completion of the Human Genome Project in 2003 set the stage for a more exploratory or agnostic approach to uncover the genetic underpinnings of drug response. In this respect, genome-wide association studies (GWAS) are now used to interrogate variants that represent a large portion of variation across the human genome and to evaluate the association between these variants and variability in drug disposition, response, and toxicity. In contrast to the candidate gene approach, GWAS require no prior knowledge of drug action in the body. Landmark human genome sequencing and haplotype mapping efforts (e.g., the HapMap and 1000 Genomes projects) have further
informed pharmacogenomic research endeavors. Along these lines, genomic technologies have evolved at a rapid pace. For example, next-generation sequencing technologies, whereby millions of DNA strands are sequenced in parallel, have resulted in substantially higher throughput than older sequencing methods. This has led to an interrogation of all nucleotide bases in the genome (i.e., whole-genome sequencing) and all nucleotide bases in the protein-coding regions of the genome (i.e., whole-exome sequencing). It is anticipated that whole-genome and whole-exome sequencing will foster the expansion of pharmacogenomic research and application by aiding in the discovery of rare and novel variants that are not captured by GWAS.

From a clinical perspective, the increasing affordability and availability of DNA microarrays provides a cost-effective mechanism for assessing thousands of variants simultaneously. This has ushered in the era of preemptive (“just in case”) genetic testing whereby DNA microarrays are used to test many variants in relevant pharmacogenes, and this information is stored electronically for future use. However, although many pharmacogenomic associations have been discovered during the past decade, only a few examples are actively being implemented in the clinical setting. Several factors influence the application of pharmacogenetic testing in clinical practice, including analytic validity (the ability of a genetic test to accurately and reliably measure the genotype of interest), clinical validity (the accuracy with which a genetic test can predict the presence or absence of the phenotype of interest), and clinical utility (the likelihood that the genetic test will lead to an improved outcome) (www.cdc.gov/genomics/gtesting/ACCE/). With respect to clinical utility, the Clinical Pharmacogenetics Implementation Consortium (CPIC) was formed as a shared project between the NIH (National Institutes of Health)-sponsored Pharmacogenomics Research Network and the Pharmacogenomics Knowledgebase, with a goal of developing peer-reviewed guidelines for certain drug-gene pairs to help clinicians understand how available genetic test results should be used to optimize drug therapy. The CPIC guideline development process uses systematic evidence review to rate the strength of recommendations.
and primarily assumes that clinical genotyping results are already available. In addition to CPIC, the Dutch Pharmacogenetics Working Group of the Royal Dutch Pharmacists Association has developed clinical practice guidelines that are based on systematic evidence reviews. Ultimately, critical care clinicians should include pharmacogenetic information in the therapeutic decision-making process with specific attention given to the strength of the available evidence, using available guidelines as a supportive framework. In the next sections, we will discuss key examples of genetic variants that influence the PK and/or PD of agents used in the ICU, together with factors that influence their clinical application (e.g., availability of evidence-based guidelines).

**IMPACT ON PK**

**CYP2D6 Polymorphisms**

Cytochrome P450 2D6 (CYP2D6) plays an important role in the metabolism and bioactivation of about one of every four drugs in clinical use, including many antidepressants (e.g., paroxetine, fluvoxamine, amitriptyline), antipsychotics (e.g., haloperidol, risperidone, clozapine), and opioids (e.g., codeine, tramadol). The CYP2D6 gene is highly polymorphic, with 120 allelic variants currently indexed by the CYP Allele Nomenclature Committee (The Human Cytochrome P450 [CYP] Allele Nomenclature Database; www.cypalleles.ki.se/). Variant CYP2D6 alleles include gene deletions, single nucleotide polymorphisms (SNPs), and copy number variations (e.g., gene duplications), among others. These polymorphic alleles translate into differences in CYP2D6 metabolizing enzyme activity and are broadly characterized as functional (normal or increased enzyme activity), reduced-function (decreased enzyme activity), or nonfunctional (inactive or no enzyme) alleles. According to the type and number of CYP2D6 alleles, individuals are assigned a CYP2D6 phenotype classification (i.e., extensive metabolizer [EM], intermediate metabolizer [IM], poor metabolizer [PM], or ultrarapid metabolizer [UM]). Individuals with the
CYP2D6 EM (i.e., “normal”) phenotype carry two functional alleles, two reduced-function alleles, one functional allele and one nonfunctional allele, or one functional allele and one reduced-function allele. Intermediate metabolizers carry one reduced-function allele and one nonfunctional allele. Poor metabolizers carry two nonfunctional alleles. Ultrarapid metabolizers carry several copies of a functional allele (e.g., as many as 13). CYP2D6 phenotypes vary by race and ethnicity. For example, the CYP2D6 PM phenotype is found in 5%–10% of whites, 0%–19% of blacks, and less than 1% of Asians. Although genotype analysis has become the method of choice to predict a person’s CYP2D6 metabolic activity status, substantial differences exist in the number of genetic variants assayed as well as in the manner in which genetic tests are interpreted. The current process for translating CYP2D6 genotype results to phenotype assignments is not universal; however, in this section, the traditional phenotype terminology (i.e., EM, IM, PM, and UM) is used.

For many CYP2D6 substrates, variation in CYP2D6 metabolizing enzyme activity is the primary factor contributing to interindividual variability in drug response. Determining an individual’s CYP2D6 metabolic activity status can help in the selection of individuals who require an alternative drug or dosage regimen. Patients with reduced-function or nonfunctional CYP2D6 enzyme (e.g., IMs or PMs) attain high parent drug concentrations with standard medication dosing and have less metabolite formation. Depending on which pharmacologic moiety is active, the outcome may be exaggerated efficacy/increased toxicity associated with the parent drug, or therapeutic failure (if it is a prodrug that must be converted to an active metabolite). In UMs, the converse can be expected (i.e., therapeutic failure if an active parent drug or exaggerated efficacy/increased toxicity if a prodrug).

Even though CYP2D6 potentially influences response or toxicity to many drugs, clinical acceptance of CYP2D6 genotyping in routine practice is currently rare outside of academic or specialty medical centers. Furthermore, evidence to support specific clinical applications for ICU patients is even less developed. However, the Pharmacogenomics Knowledgebase (www.pharmgkb.org) currently
lists 34 different CPIC guidelines to help manage drug-gene interactions for CYP2D6 (Table 51.1). In addition, a summary of commonly used drugs in the critical care setting with pharmacogenetic associations is provided in Table 51.2.

Box 51.1. Glossary of Genomics Terms\textsuperscript{1,2}

Allele: One of two or more alternative forms of a gene that arise by inheritance and that are found at the same location on a chromosome. For most autosomal genes, an individual will have two alleles, one inherited from the mother and one inherited from the father.

Autosomal trait: A trait caused by a chromosome that is not a sex chromosome.

Candidate gene study: An evaluation of prespecified genetic variants and their association(s) with a phenotypic trait or disease. This approach requires prior knowledge of the likely mechanisms underlying drug disposition, response, or toxicity.

Diplotype: A pair of haplotypes, with one haplotype inherited from the mother and one haplotype inherited from the father.

DNA microarray: Solid support on which thousands of DNA sequences from different genes are attached. This technology is used to genotype many (e.g., thousands) variants at one time. DNA microarrays that are specifically designed to interrogate single nucleotide polymorphisms (SNPs) are known as SNP arrays.

Genetic variant: A difference in DNA sequence compared with a reference sequence.

Genome: Complete set of genetic material for an organism.

Genome-wide association study: An evaluation of variants that
represent a large portion of variation across the human genome and their associations with a phenotypic trait or disease. This approach does not require prior knowledge of the mechanisms underlying drug disposition, response, or toxicity.

Genotype: Broadly defined, the genetic makeup of an organism with reference to a single trait or set of traits. This term is also used to describe the combination of alleles an individual inherits at a specific region of DNA.

Genotyping: Laboratory testing that reveals the specific alleles inherited by an individual at a particular region of DNA.

Haplotype: Set of closely linked alleles that are located on one chromosome and inherited together as a unit or “block.”

Homozygous: The same alleles at a specific region of DNA.

Heterozygous: Different alleles at a specific region of DNA.

Linkage disequilibrium: Nonrandom association of alleles at different loci on the same chromosome.

Mutation: A genetic variant that is rare, often defined as occurring in less than 1% of the population. Mutations are often associated with genetic diseases, such as cystic fibrosis or sickle cell anemia.

Pharmacogenomics: Study of the relationship between variants in a large collection of genes, up to the whole genome, and variability in drug disposition, response, and toxicity.

Phenotype: The set of measurable characteristics of an individual caused by genotype, environment, or a combination of both.

Polymorphism: A genetic variant that is common, often defined as occurring in 1% or more of the population.
Single nucleotide polymorphism (SNP): Difference in one nucleotide (base pair) in a DNA sequence. SNPs are the most common type of polymorphism in the genome.

Wild type: A characteristic that refers to the typical form of a trait as it occurs in nature. Also called the most common allele in a population.

Although no CPIC guideline currently exists, a gene-drug interaction of particular interest to critical care clinicians is CYP2D6 and haloperidol, given the common use of this drug to treat delirium. Haloperidol clearance has been directly correlated with the number of functional CYP2D6 genes in psychiatric patients. In general, studies have found that CYP2D6 PMs receiving haloperidol have a greater incidence of ADRs, including pseudoparkinsonism (increased sum of extrapyramidal symptom scores; p=0.02), a prolonged elimination half-life (19.1 ± 3.6 vs. 12.9 ± 4.0 hours, p=0.04), and a lower apparent oral clearance (12.8 ± 4.1 vs. 27.0 ± 11.3 mL/minute/kg, p=0.02), than do EMs. However, additional factors (i.e., smoking status and body weight) also contribute to the observed ADRs.

Although haloperidol is a useful example, the prescribing of risperidone for psychosis and other behavioral disorders is increasingly common. In studies involving risperidone, the CYP2D6 PM phenotype was associated with a moderate-to-marked increase in drug discontinuation attributable to ADRs (namely pseudoparkinsonism). Pharmacokinetic analyses support these observations, with evidence that PMs have a 63% decrease in the metabolism and fraction of the active metabolite.

Studies exploring the impact of CYP2D6 polymorphisms on variability in toxicity or response to cardiovascular drugs (i.e., β-blockers) also suggest a need for individualized therapy. One large population-based study reported that CYP2D6 PMs receiving β-blockers metabolized by CYP2D6 (e.g., metoprolol, carvedilol, nebivolol, propranolol, and alprenolol) had a significantly lower heart
rate and diastolic blood pressure than EMs, which was not reproduced in patients receiving β-blockers not metabolized by CYP2D6 (e.g., atenolol).

Understanding opioid metabolism and disposition is essential for assessing the risk of toxicity and, in some cases, for providing additional information regarding the risk of therapeutic failure. Opioids significantly metabolized by the CYP enzyme system may be subject to drug-gene interactions. Codeine provides a good example of the potential clinical utility of CYP2D6 genotyping. Codeine, a prodrug, is metabolized by CYP2D6 to form morphine. CYP2D6 PMs do not effectively convert codeine to morphine, resulting in decreased analgesic effects compared with EMs. Conversely, CYP2D6 UMs have increased conversion of codeine to morphine compared with EMs, as well as an increased risk of morphine toxicity and a clinically significant risk of severe morbidity and mortality.

Opioids (codeine, tramadol, oxycodone)  CYP2D6

UMs: Monitor serum concentrations to ensure effectiveness (especially for invasive fungal infections in immunocompromised patients)\textsuperscript{21,22}

UMs: Analgesia: Select alternative drug (e.g., acetaminophen, NSAID, morphine—not tramadol or oxycodone), or be alert to symptoms of insufficient pain relief\textsuperscript{9,14,23}

PMs and IMs: Analgesia: Select alternative drug (e.g., acetaminophen, NSAID, morphine—not tramadol or oxycodone), or be alert to ADRs. Cough: Be extra alert to ADRs caused by increased morphine plasma concentrations\textsuperscript{9,14,23-27}

IM = intermediate metabolizer; PM = poor metabolizer; QTc = corrected QT interval; UM = ultrarapid metabolizer.

Patient response to tramadol, an alternative opioid agent commonly used for pain management, is also affected by CYP2D6 genotype, with CYP2D6 PMs at risk of insufficient analgesia and UMs at risk of serious ADRs (e.g., respiratory depression).\textsuperscript{6,33} The extent to which other opioids (e.g., hydrocodone, oxycodone) are affected by CYP2D6 variation is under investigation. Preliminary evidence suggests that CYP2D6 PMs have lower peak concentrations of hydromorphone after a dose of hydrocodone; however, CYP2D6 metabolizer status does not appear to affect response to hydrocodone therapy. Similarly, CYP2D6 PMs have lower peak concentrations of oxymorphone after a dose of oxycodone than do EMs.\textsuperscript{34} However, discordant findings from prospective clinical studies currently suggest limited clinical utility of CYP2D6 genotyping for oxycodone therapy. In general, the CPIC guidelines recommend that opioids not metabolized by CYP2D6, including morphine, oxymorphone, buprenorphine, fentanyl, methadone,
and hydromorphone, together with nonopioid analgesics, be considered as alternatives for use in CYP2D6 PMs and UMs according to the type, severity, and chronicity of the pain being treated.\textsuperscript{9}

Antiemetic therapy—particularly with ondansetron—is the last example for clinical utility of the CYP2D6 genotype in critically ill patients. Patients having CYP2D6 EM, IM, or PM phenotypes are more likely to have an increased response to ondansetron than are patients having CYP2D6 UM phenotypes. This increased response leads to a reduced risk of vomiting after chemotherapy or anesthesia. However, no significant associations have been found for nausea.\textsuperscript{35,36}

**CYP2C9 Polymorphisms**

Cytochrome P450 2C9 is another drug-metabolizing enzyme involved in the phase I metabolism of about 10% of drugs, including oral anticoagulants (e.g., warfarin), antiepileptics (e.g., phenytoin), oral antidiabetics (e.g., glyburide), NSAIDs (nonsteroidal anti-inflammatory drugs) (e.g., celecoxib), and anti-infectives (e.g., sulfamethoxazole).\textsuperscript{37-39}

Several variants have been identified in the CYP2C9 gene that influence CYP2C9 metabolizing enzyme function. CYP2C9*1 is the normal-activity allele, and CYP2C9*2 and CYP2C9*3 are the most commonly studied decreased-function alleles. CYP2C9*2 is present in about 13%, 0%, and 3% of whites, Asians, and blacks, respectively. CYP2C9*3 is present in about 7%, 4%, and 2% of whites, Asians, and blacks, respectively.\textsuperscript{39} An individual carrying two normal-activity alleles (i.e., *1/*1) is assigned the EM phenotype. An individual carrying one normal-activity allele and one decreased-function allele (i.e., *1/*2 or *1/*3) is assigned the IM phenotype. An individual carrying two decreased-function alleles (i.e., *2/*2, *2/*3, or *3/*3) is assigned the PM phenotype.\textsuperscript{39}

To date, warfarin has been heavily studied with respect to CYP2C9 genetics because of its frequent use and narrow therapeutic index. The FDA's Adverse Event Reporting System affirms that ADRs attributable to warfarin are common; in fact, warfarin is among the top 10 most
commonly reported drugs during the past 20 years.\textsuperscript{40} CYP2C9 genotype accounts for 9%–12% of the observed variance in warfarin maintenance dose requirements.\textsuperscript{41} In general, individuals carrying CYP2C9*2 or *3 alleles have lower warfarin dose requirements and a longer time to achieve a therapeutic international normalized ratio (INR) than do EMs.\textsuperscript{42} A recent retrospective study found that patients carrying variant CYP2C9 alleles (e.g., *2, *3) had a significantly increased risk of serious or life-threatening bleeding events after warfarin therapy.\textsuperscript{43} However, a prospective study revealed conflicting data showing no association between variant CYP2C9 alleles and the risk of warfarin-associated bleeding.\textsuperscript{44} Depending on the approach to initiating anticoagulation in clinical practice, CYP2C9 genotype is a factor to consider for warfarin, in addition to VKORC1 (drug target) genotype, drug-drug interactions, drug-disease interactions, and drug-diet interactions. The practicalities and controversies of warfarin genotyping in clinical practice are discussed in more detail in the VKORC1 section.

A CYP2C9 drug-gene interaction also exists for phenytoin, one of the most commonly used antiepileptics in the ICU. Phenytoin clearance through CYP2C9-mediated hydroxylation is a primary mechanism, although at high concentrations, CYP2C19 is also involved. Many studies have reported higher phenytoin plasma concentrations and lower phenytoin dose requirements in CYP2C9 variant allele carriers (i.e., IMs or PMs) than in EMs. In this respect, CYP2C9 genotype–guided dose adjustments have been recommended for phenytoin therapy (e.g., 25% dose reduction for IMs and 50% dose reduction for PMs).\textsuperscript{39} Despite this information, data supporting the link between altered phenytoin plasma concentrations and ADRs are lacking, presumably because of the nonlinear, saturable PK, and auto-inductive effects of this drug.

**CYP2C19 Polymorphisms**

Cytochrome P450 2C19 is responsible for the metabolism of antiplatelet agents (e.g., clopidogrel), proton pump inhibitors (e.g.,
lansoprazole, omeprazole), antidepressants (e.g., amitriptyline, citalopram, sertraline), and antifungal agents (e.g., voriconazole). The CYP2C19 gene is highly polymorphic, with SNPs that result in decreased or increased CYP2C19 metabolizing enzyme activity. CYP2C19*1 is the normal-activity allele, CYP2C19*2 and CYP2C19*3 are loss-of-function (i.e., decreased or no function) alleles, and CYP2C19*17 is an increased-function allele. An individual with two normal-function alleles (i.e., *1/*1) is assigned the EM phenotype. An individual with one normal-function allele and one loss-of-function allele (e.g., *1/*2 or *1/*3) is assigned the IM phenotype. An individual with two loss-of-function alleles (e.g., *2/*2 or *3/*3) is assigned the PM phenotype. An individual carrying two increased-function alleles (e.g., *17/*17) or one normal-function allele and one increased-function allele (e.g., *1/*17) is assigned the UM phenotype. The frequency of the CYP2C19 PM phenotype is 2%–5% in whites, 2%–5% in African Americans, and 15% in Asians. The frequency of the CYP2C19*17 allele is about 22% in whites, 19% in African Americans, and 17% in Asians (South/Central). The impact of the CYP2C19 genotype on clinical outcomes associated with clopidogrel anti-platelet therapy has received much attention in patients with acute coronary syndromes. Clopidogrel undergoes a two-step bioactivation process to form an active thiol metabolite. The CYP2C19 enzyme is important in each step of this process. Clopidogrel response varies widely in the general population, and many studies have shown that CYP2C19*2 carriers (e.g., *1/*2 or *2/*2 genotypes) have lower concentrations of the clopidogrel active metabolite and higher on-treatment platelet aggregation than non-carriers. In addition, several studies link CYP2C19 PM and IM status to an increased risk of major adverse cardiovascular events in clopidogrel-treated patients with acute coronary syndromes, likely because of reduced formation of the active clopidogrel metabolite. Although the primary concern in this respect is loss of efficacy, CYP2C19 UMs may be at higher risk of ADRs (e.g., hemorrhage), likely because of increased formation of the active clopidogrel metabolite. The primary takeaway is that variability in response to clopidogrel treatment associated with an
increased risk of death or thrombotic recurrences is present in 5%–40% of patients treated with conventional doses of clopidogrel, with a multifactorial etiology that includes genetic polymorphisms and nongenetic factors (e.g., comorbidities, drug-drug interactions, age).\textsuperscript{55}

Another relevant example of the application of CYP2C19 pharmacogenetics to critical care is in the use of proton pump inhibitors. The CYP2C19 genotype is responsible for 80% of the metabolism of omeprazole, lansoprazole, and pantoprazole.\textsuperscript{17,56,57} Clinical data show that CYP2C19 PMs have 4- to 15-fold higher plasma concentrations of omeprazole and lansoprazole, and superior acid suppression, relative to EMs.\textsuperscript{17} Having CYP2C19 IM or PM status may lead to enhanced proton pump inhibitor–mediated Helicobacter pylori eradication and ulcer healing; however, a consistent demonstration of improved outcomes relative to the CYP2C19 phenotype remains elusive. Future research endeavors are needed to firmly establish the clinical utility of CYP2C19 genotyping for the proton pump inhibitors; however, when preemptive testing is available, clinicians may consider relevant drug-gene interactions for individual patient management.

Voriconazole is a narrow therapeutic index antifungal agent with nonlinear PK whose plasma exposure is influenced, in part, by CYP2C19 metabolizer status.\textsuperscript{21} For example, in healthy volunteers, CYP2C19 PMs had 4-fold higher voriconazole exposure than EMs.\textsuperscript{58} Although CPIC has not yet developed guidelines for this drug, the Dutch Pharmacogenetics Working Group guidelines recommend the monitoring of voriconazole serum concentrations in CYP2C19 IMs and PMs. This will help minimize the risk of concentration-dependent ADRs. In addition, knowledge of CYP2C19 UM status may help prevent therapeutic failure caused by inadequate drug concentrations.\textsuperscript{21} Given the high costs associated with hospitalization for treatment-resistant invasive fungal infections, health systems are increasingly considering CYP2C19 genotyping and therapeutic drug monitoring for voriconazole therapy to prevent avoidable health care use.\textsuperscript{20,22}

\textbf{CYP3A Polymorphisms}
Tacrolimus is a calcineurin inhibitor immunosuppressant commonly used in solid organ and hematopoietic stem cell transplantation. Tacrolimus has a narrow therapeutic range and large interpatient variability in the dose required to achieve therapeutic trough concentrations. Low tacrolimus exposure may increase the risk of graft rejection, whereas high tacrolimus exposure may increase the risk of ADRs (e.g., nephrotoxicity, neurotoxicity, hyperglycemia). Tacrolimus is predominantly metabolized by CYP3A5 and, to a lesser extent, by CYP3A4. The CYP3A5 gene contains several variants, *3, *6, and *7, which result in loss of protein expression or nonfunctional protein. Individuals carrying two copies of the CYP3A5*1 allele (CYP3A5 *1/*1) are assigned the expresser (EM) phenotype. An individual carrying one functional allele and one nonfunctional allele (i.e., *1/*3, *1/*6, or *1/*7) is assigned the expresser (IM) phenotype. An individual carrying two nonfunctional alleles (e.g., *3/*3, *6/*6) is assigned the non-expresser (PM) phenotype. Substantial differences in CYP3A5 variant allele frequencies exist on the basis of race. For example, CYP3A5*3 is present in 92% of whites, 32% of African Americans, and 74% of Asians.

Therapeutic drug monitoring is routinely used to manage tacrolimus blood concentrations in clinical practice, but therapeutic drug monitoring does not identify the optimal starting dose of tacrolimus for an individual patient. Several studies, in various transplant populations, have shown that CYP3A5 expressers have lower dose-adjusted tacrolimus trough concentrations than do CYP3A5 nonexpressers. In this respect, a prospective study of kidney transplant recipients showed that CYP3A5 genotype-guided tacrolimus dosing resulted in a significantly higher percentage of patients with tacrolimus in the target range 3 days after initiating therapy compared with the control arm (43.2% vs. 29.1%, respectively). This study did not show a significant difference in clinical outcomes (e.g., acute rejection) between genotype-guided and standard tacrolimus dosing. However, a recent meta-analysis of kidney transplant recipients showed a modestly increased risk of acute rejection in CYP3A5 expressers (odds ratio 1.32, p=0.04). According to the CPIC guidelines, no definitive
evidence exists to indicate that CYP3A5 genotype–guided tacrolimus dosing improves long-term clinical outcomes. However, the clinical utility of CYP3A5 genotyping appears to be in the ability to more effectively achieve target trough tacrolimus concentrations, particularly at the initiation of therapy.\(^\text{59}\) In this respect, CPIC guidelines recommend that CYP3A5 expressers (EMs or IMs) receive 1.5–2 times the recommended tacrolimus starting dose, not to exceed 0.3 mg/kg/day. In contrast, it is recommended that CYP3A5 non-expressers (PMs) start therapy with standard recommended doses. In both cases, therapeutic drug monitoring should be used to guide dose adjustments. These recommendations apply to the use of tacrolimus in patients with kidney, heart, lung, and hematopoietic stem cell transplants and in patients with liver transplants when the donor and recipient genotypes are identical. In sum, CYP3A5 genotyping may be most helpful to guide initial tacrolimus dosing in the hopes of more rapidly achieving target trough concentrations.\(^\text{59}\) Genetic testing does not preclude the need for therapeutic drug monitoring or the need to consider other patient-specific factors that may influence tacrolimus therapy (e.g., age, drug-drug interactions).

**N-Acetyltransferase 2**

N-acetyltransferase 2 is a phase II drug-metabolizing enzyme that acetylates several agents, including isoniazid, hydralazine, procainamide, phenelzine, dapsone, and sulfonamides. Observations that some patients receiving isoniazid were more prone to peripheral neuropathy led to identification of the slow acetylator phenotype. Across the general population, phenotype frequencies vary among different ethnic populations (e.g., about 50% of whites are slow acetylators, whereas the frequency is much lower in Asians). For critically ill patients, slow acetylators have an increased risk of immune-mediated toxicity (systemic lupus erythematosus) with specific agents used in the ICU (i.e., hydralazine, procainamide, and sulfamethoxazole). In addition, fast acetylators may carry a higher risk of preventable ADRs. For example, procainamide, which is bio-
activated in vivo to a pharmacologically active class III antiarrrhythmic metabolite, N-acetylprocainamide, increases the risk of torsades de pointes—especially in renally compromised patients. Because procainamide is still used in specific clinical scenarios (e.g., rate control for patients with Wolff-Parkinson-White syndrome and atrial fibrillation), N-acetyltransferase 2 phenotype remains important to evaluate as a clinical consideration.\textsuperscript{64,65}

\textbf{SLCO1B1 Genotype}

Statins are widely used lipid-lowering agents with a proven record for reducing cardiovascular morbidity and mortality. Statins are associated with myalgias, myopathy, and, rarely, rhabdomyolysis. Mechanisms leading to increased risk of statin-induced myopathy have been incompletely characterized and are likely multifactorial—including comorbidities, presence of significant drug-drug interactions, and genetic variation. Several clinical factors are associated with statin-induced myopathy, including advanced age, slight body mass index, female sex, metabolic comorbidities, drug-drug interactions, hypothyroidism, and Asian ancestry.\textsuperscript{66}

Statin dose remains perhaps the strongest predictor of statin-induced myopathy, with a reported incidence that is almost 10-fold higher in patients on high-dose statin therapy. Although this dose-dependent relationship appears to be a class effect for statins, evidence suggests that this effect is most clinically significant with respect to simvastatin.\textsuperscript{67}

Of importance, statins are substrates of the organic anion transporting polypeptide 1B1 (OATP1B1), an up-take transporter located on the basolateral surface of hepatocytes. Variation in SLCO1B1, the gene that encodes OATP1B1, produces a defective transport protein, which increases systemic exposure and toxicity.\textsuperscript{68-70} A GWAS identified a significant association between the functional SLCO1B1 c.521T>C SNP and simvastatin-induced myopathy, showing a 4.5-fold increased risk in heterozygotes and a 16.9-fold increased risk in variant homozygotes.\textsuperscript{71} The c.521 T>C SNP is contained in the
SLCO1B1*5 haplotype, which is carried in about 1%–3% of whites, up to 2% of Africans, and up to 1% of Asians, and also in the SLCO1B1*15 haplotype, which is carried in about 14% of whites, 3% of Africans, and up to 13% of Asians. CPIC guidelines exist for simvastatin dosing in relation to SLCO1B1 c.521 T>C genotype. Specifically, individuals with SLCO1B1 c.521 T/T (normal function) genotype have a normal simvastatin-induced myopathy risk and may be prescribed the desired starting dose, with doses adjusted on the basis of disease-specific guidelines. Individuals with the SLCO1B1 c.521 T/C (intermediate function) genotype have an intermediate simvastatin-induced myopathy risk. CPIC guidelines recommend a lower simvastatin dose or consideration of an alternative statin (e.g., pravastatin or rosuvastatin). Finally, individuals with the SLCO1B1 c.521 C/C (low function) genotype have a high simvastatin-induced myopathy risk. It is recommended that these patients be prescribed a lower dose or that an alternative statin be considered (e.g., pravastatin or rosuvastatin). In each case presented, the FDA recommends against simvastatin 80 mg/day unless the dose has already been tolerated for 12 months.

IMPACT ON PD

VKORC1 Polymorphisms

The vitamin K epoxide reductase (VKOR) enzyme catalyzes the recycling of reduced vitamin K, which is essential for the formation of clotting factors II (prothrombin), VII, IX, and X. Warfarin inhibits this enzyme, thereby producing anticoagulant effects. Many common SNPs exist in VKORC1, the gene encoding VKOR. The g.-1639G>A SNP is contained in a haplotype associated with reduced VKOR expression. Individuals with this SNP are more sensitive to warfarin, as evidenced by decreased therapeutic dose requirements (28% smaller per allele carried). In addition to CYP2C9 polymorphisms, VKORC1 genotype is an important consideration for predicting warfarin dose requirements and accounts for 25%–30% of observed dose variance in white
populations. In addition, combining VKORC1 and CYP2C9 genotypes explains up to 59% of the variability in warfarin dose requirements. Two GWAS analyzing hundreds of thousands of SNPs across the human genome further confirmed that VKORC1 and CYP2C9 provide the greatest contributions to warfarin dose variability in whites. Although variation in both genes has been associated with excessive anticoagulation, VKORC1 variants, unlike CYP2C9, have not been associated with an increased risk of hemorrhage.73-76

Two recent randomized trials evaluating the clinical impact of genotype-guided warfarin dosing are the European Pharmacogenetics of Anticoagulant Therapy (EU-PACT) trial and the Clarification of Optimal Anticoagulation Through Genetics (COAG) trial. Both trials examined the effects of genotype-guided warfarin dosing compared with empiric dosing strategies; however, only the EU-PACT study showed an overall improvement in time to achieve therapeutic INR, which was shorter in the genotyping arm (21 vs. 29 days; p<0.001).

The primary outcome of the COAG trial was to assess the percentage of time in therapeutic range within the first 4 weeks of therapy. Results indicated that 45% of patients in both arms reached therapeutic INR levels within 4 weeks, and there were no differences in bleeding or thromboembolic events. About one-third of the patients were African Americans, and the percentage of time in therapeutic range within the African American subgroup who received dosing on the basis of clinical variables was 43.5%, whereas in the genotyping arm, the percentage of time in therapeutic INR was 35%, favoring clinical-variable dosing versus genotyping dosing in African Americans (p=0.01). Of importance, 76% of African Americans (compared with 25% of non–African Americans) had no genetic variation in the SNPs assessed, and other variants known to predict dosing variability in African Americans (e.g., CYP2C9 *5, *6, *8, and *11) were not assayed in the COAG trial.77,78 Taken together, including the pharmaco-genetic information for warfarin in a systematic approach to assessing and treating critically ill patients on the basis of available evidence and expert opinion could help avoid dosing errors that may adversely affect patient outcomes.
**Human Leukocyte Antigens**

Human leukocyte antigen class I and class II constitute the major human histocompatibility complex and assist in the initiation of the immune response by presenting antigens to T cells. Three different genes (HLA-A, HLAB, and HLA-C) exist within class I. The HLA-B genes are highly polymorphic and have been strongly associated with ADRs. Stevens-Johnson syndrome and toxic epidermal necrolysis caused by therapy with the antiepileptic drug carbamazepine have been linked to the HLAB*15:02 genotype—particularly in Han Chinese. Because of the relatively high prevalence of this allele in Han Chinese and other Asian populations, the FDA recommends HLA-B*15:02 screening for all patients of Asian ancestry before initiating carbamazepine.

Another strong link between HLA genotype and ADRs is shown by abacavir hypersensitivity associated with the HLA-B*57:01 allele. Although this anti-HIV medication is not commonly used in the ICU, it provides the clearest evidence to date of the clinical utility of a pharmacogenetic biomarker for preventing ADRs. About 5%–8% of patients have a limiting hypersensitivity reaction to abacavir within the first 6 weeks of therapy. The HLAB*57:01 variant is found in 8% of whites, but it is rare in African American and Asian populations. The Prospective Randomized Evaluation of DNA Screening in a Clinical Trial (PREDICT-1) was conducted in 1,956 patients across 19 countries to determine the effectiveness of HLA-B*57:01 screening to prevent hypersensitivity. Results showed that prospective screening for the HLA-B*57:01 allele in the predominantly white population prevented 100% of abacavir hypersensitivity reactions. These results and similar data from a case-control trial involving nonwhite populations led to the formal recommendation of pretreatment screening for HLA-B*57:01 in the current HIV treatment guidelines. Future research will likely elucidate additional HLA variants that underlie drug hypersensitivity reactions, which is a pertinent critical care issue.

**KCNH2, Other Cardiac Ion Channels, and Associated**
Proteins

KCNH2, otherwise known as the human ether-a-go-go-related gene, encodes for a potassium voltage-gated ion channel responsible for the rapid component of the delayed rectifier current (IKr) in cardiac cells. Mutations in KCNH2 reduce cardiac repolarizing current, prolong the action potential, and are a cause of congenital long-QT syndrome. Virtually all drugs that prolong the QT interval and cause the potentially fatal arrhythmia called torsades de pointes also block the IKr/human ether-a-go-go-related gene channel. The list of offending drugs is large and includes many drugs commonly prescribed in the ICU, such as antiarrhythmics (quinidine, disopyramide, procainamide, dofetilide, ibutilide, sotalol, and amiodarone), antibiotics (erythromycin, clarithromycin, sparfloxacin, and pentamidine), antiemetics (droperidol), antipsychotics (haloperidol, thioridazine, chlorpromazine, mesoridazine, and pimozide), bepridil, methadone, among others. The incidence of torsades de pointes in those receiving antiarrhythmics has been estimated to be as high as 5%, and although some clinical risk factors have been identified, the ADR remains unpredictable for individual patients. Several studies support the involvement of variation in KCNH2 and other cardiac ion channel–associated genes. In one of the larger studies, Yang et al. screened 92 patients with drug-induced long-QT syndrome and found that 10%–15% of individuals carried a mutation in the coding region of at least one of a series of sodium or potassium channel genes (KCNH2, KCNQ1, SCN5A, KCNE1, or KCNE2). Similarly, KCNE1, KCNE2, and KCNH2 variants were identified in 4 of 32 patients with drug-induced long-QT syndrome evaluated in another study. Two very large European ancestry GWAS further identified some of these ion channel genes as being important determinants of QT interval variability. Further studies are needed to define the relative importance of these genes and to determine the strength of the association of specific variants with an increased risk of drug-induced long-QT syndromes in critically ill patients.86-91

Tumor Necrosis Factor Alpha and Sepsis
Sepsis syndrome is one of the most common causes of morbidity, mortality, and resource expenditure in critically ill patients.\textsuperscript{92} In this complex syndrome, invasive infection, trauma, or other insults elicit an abnormal host inflammatory response that, in a minority of patients, gives rise to profound hemodynamic instability (septic shock), organ failure, and death. The principal focus of clinical investigation in this area is based on attempts to understand the host inflammatory response and to develop interventions to modulate such response. Common variants present in genes encoding inflammatory mediators could affect the regulation of the inflammatory response. A SNP in the tumor necrosis factor alpha (TNFA) gene g.-308G>A has been among the most thoroughly studied in this context. Mira et al. reported that the g.-308A allele (also known as TNF2) was more common in patients with sepsis and was associated with a significantly increased risk of mortality compared with case-matched controls.\textsuperscript{93} Similarly, O'Keefe et al. reported that the presence of TNF2 was associated with an increased risk of the development of sepsis, but not mortality, after severe injury in a cohort of patients.\textsuperscript{94} In contrast, Tang et al. reported that TNF2 occurred with no greater frequency in patients with sepsis than in patients without sepsis. However, for the subset of patients who developed shock, this genetic variant was associated with an increased rate of mortality.\textsuperscript{95} Inconsistent findings in studies examining the clinical significance of the TNFA g.-308G>A SNP in patients with sepsis or those at risk of this disease are representative of problems with gene-association studies in general. Systematic analyses of studies trying to link genetic variants to complex traits have shown that the significant results reported in the initial studies are often not replicated in subsequent experiments. Linkage-disequilibrium studies can be confounded because the effects of variants in a locus of interest (for example, the TNFA g.-308 SNP) may be influenced by the effects of adjacent variants (e.g., those present elsewhere in the TNFA gene), genetic variants present in independently segregating loci (e.g., those encoding other inflammatory mediators), and nongenetic factors. For the critically ill individual, these nongenetic factors include the nature and location of the inciting infection, the manner in which supportive
care is provided, and the age and premorbid health status of the patient. In addition, populations studied in many trials are heterogeneous. In the reports cited, populations differed substantially with respect to geography as well as in their underlying clinical condition. The challenge for critical care investigators will be to design gene-association studies that are both appropriately controlled and of sufficient power so that the genetic determinants of disease susceptibility and drug effect can be measured accurately.\textsuperscript{96-98}

**INCORPORATING PHARMACOGENOMICS INTO PATIENT CARE**

Despite the many established associations between genetic variants and drug response, pharmacogenomic testing and genotype- or phenotype-based prescribing have not been widely implemented in clinical practice. Drug, patient, research design, regulatory, and practical issues currently limit the integration of pharmacogenomics into the clinical setting, including the ICU. Regarding drug factors, knowledge that an enzyme is involved in the metabolism of a drug and that a genetic variant exists is not sufficient to recommend genetic testing. The functional consequences of the variant, the quantitative role of the gene product to the drug’s overall PK and PD, and the agent’s therapeutic index must be considered. Clopidogrel, for example, is metabolized by several CYP enzymes, yet only CYP2C19 variants are important for the increased risk of major adverse cardiovascular events. Few examples currently exist in which a drug-ADR relationship can be predicted by variation at a single gene locus (e.g., abacavir and HLA-B*57:01). In contrast, most drug response and toxicity examples (e.g., torsades de pointes or warfarin dose-response) are polygenic. Drugs may also have a wide therapeutic index or a toxicity that is mild or easy to detect, suggesting that genotyping is not necessary, such as with CYP2D6 polymorphisms and β-blockers. Drugs that are pharmacologically active themselves and that have active metabolites, such as some tricyclic antidepressants, also complicate efforts to associate genetic variants with ADRs. Many
patient issues facing the critically ill are known to produce wide variability in drug response and ADR risk. In addition to considering genetic variation, multidisciplinary critical care teams must evaluate the impact of impaired organ function, comorbidities, polypharmacy, drug interactions, and many other factors when providing pharmacotherapy. The paucity of pharmacogenomic research involving critically ill patients undermines an appreciation of the potential role that genetics play in this population. Of the 107 pharmacogenomic studies currently listed as seeking volunteers in an online repository of human clinical studies being conducted globally, most involve oncology drugs. Only one study specifically mentions recruiting in the ICU, and 14 studies involve drugs with relevance to critically ill patients. Future investigations must determine the relative contribution of genetics to overall drug response and ADR risk in the critically ill in order to advance pharmacogenomics in the ICU setting.

Practical issues also hamper the widespread clinical adoption of genotyping. Medical education has not kept up with the rapid pace of pharmacogenomics. Citing this, recommendations for bolstering training in medical, pharmacy, and nursing schools globally have been advanced. An urgent need also exists for reliable bedside genetic testing because the turnaround time for tests that must be sent to accredited laboratories is not ideal. For example, according to the manufacturer, AmpliChip results can be generated in 8 hours, with the printed report received within several days. This time interval is problematic when appropriate drug dosing is needed immediately, such as with clopidogrel after myocardial infarction. It is less of an issue for long half-life drugs used for chronic therapy, such as warfarin, because algorithms have been created for dose modification once genetic information becomes available. Furthermore, alternative therapies with more favorable safety profiles and less monitoring than warfarin exist. As these issues are resolved, it is likely that more data from studies evaluating genetic predisposition to ADRs will be implemented in ICU clinical practice. Critical care practitioners should continue to be aware of new data and advances in the field of pharmacogenomics to appreciate the contribution that genetic variation makes to
interindividual variation in drug disposition, response, and toxicity.

SUMMARY

Critically ill patients have an increased risk of ADRs. Although many factors contribute to the variation in patient response to pharmacotherapy, the impact of genetic variation on drug PK and PD is increasingly being appreciated. Clinical pharmacogenomics provides critical care practitioners with additional tools to optimize medication effectiveness and improve safety profiles for the armamentarium of medications used in the critical care setting.
